Before ancient people had any idea of microorganisms, they were using them to ferment foods. Bacteria, yeast, and molds are now used extensively to preserve foods and improve their aroma and flavor. Beer is probably the oldest fermentation product consumed by humans. Its history has been traced back to the Sumerians in 7500 B.C.E. The basic component of beer is a grain or cereal, for example, malted barley, rice, corn, or millet. The major food source in cereals is starch. Barley is germinated to produce starch-degrading enzymes, or amylases. This mixture, "malt," is used to process the starch in barley or other cereals; starch must be broken down into sugar for fermentation to take place. Strains of *Saccharomyces cerevisiae* are used for lager-style beers, and strains of *S. uvarum* for ales. Wine, also an ancient beverage, is made by inoculating fruit juice, usually grape juice, with strains of *S. cerevisiae*, fermenting the high level of sugar in the juice. Many kinds of lactic-acid bacteria (LAB) are also found during yeast fermentation: *Lactobacillus* spp., *Leuconostoc* spp., and *Pediococcus* spp. Winemakers often inoculate their wines with commercial LAB cultures to reduce overly high acidity of juice (grape juice, for example, has a pH of 3.0 to 3.8) and, through their metabolism, to add flavors or "complexity" to the wine.

The bacteria that Pasteur identified as wine spoilers, the acetic-acid bacteria, are used to make vinegar. Wine or cider is inoculated with *Acetobacter* spp., which produce acetic acid by oxidizing ethanol.

Basic bread is made by adding water and salt to wheat flour. Yeast is added to "leaven" bread. The Egyptians obtained yeast from beer vats to leaven their bread. The Greeks and Romans used yeast from wine vats. Now,

## SALMON COLOR

Farmed salmon are pale in color. The color of wild salmon comes from their consumption of crustaceans in the ocean. A red yeast, *Phaffia rhodozyma*, is now fed to farmed salmon to color them red. The red pigment in the yeast, astaxanthin, is a carotenoid similar to that found in lobsters.

strains of *S. cerevisiae* are used to ferment the sugars in bread dough. LAB are also used to give special flavors to some breads: for example, *Lactobacillus sanfrancisco* for sourdough and *Lactobacillus plantarum* for rye bread.

LAB are most important in dairy products. In 1878, Joseph Lister (1827–1912) isolated, in pure culture, a bacterium that caused milk souring. LAB are used to curdle milk for cheese production, and to ripen certain cheeses (*Propionibacterium* spp., for instance, for Swiss cheese). LAB are also used in the production of yogurt, buttermilk, and kefir, an alcoholic fermented-milk product. Molds, mainly of the penicillia family, are used to break down the fats in cheese and add distinctive flavors, for example, *Penicillium roqueforti* in Roquefort cheese.

Plant material is fermented to make pickled vegetables, sauerkraut, Spanish-style olives, and soy sauce. LAB, for example, are used to ferment cabbage into sauerkraut. Several genera of bacteria, including LAB, and fungi are used to ferment olives, which are inedible before this processing.

Many fermented products are made in the Far East, often from soybean meal. A *koji*, or mixed culture of bacteria, yeast, and molds, is used to inoculate the food. For soy sauce, for example, soybean meal is inoculated with a *koji* containing *Aspergillus oryzae* and LAB such as *Lactobacillus delbrueckii*. Other common fermented-soybean foods are tempeh, miso, and *sufu* (a traditional Chinese cheeselike product). The acids these microorganisms produce, chiefly acetic, butyric, and lactic, prevent the growth of most other microorganisms. The fermentations not only favorably modify flavors and textures, but also have preservative action.

A bacterium, *Xanthomonas campestris*, produces a polymer, xanthan gum, which is used as a thickener in such foods as salad dressings, cottage cheese, yogurt, ice cream, and frostings.

## Harmful Microorganisms

Bacteria, viruses, and protozoa that cause gastroenteritis are transmitted by the fecal–oral route—that is, by the consumption of food or water fecally contaminated by

infected persons. The major bacteria that cause gastroenteritis are *Salmonella* spp., *E. coli*, *Campylobacter jejuni*, *Vibrio parahaemolyticus*, and *Yersinia enterocolitica*. Ingesting toxins produced by bacteria that have grown in food can also result in gastroenteritis. Bacteria that cause gastroenteritis by producing toxins are *Staphylococcus aureus*, *Clostridium perfringens*, and *Bacillus cereus*. Rotavirus and the Norwalk virus group are the two major viruses causing gastroenteritis.

Milk is pasteurized to eliminate *Mycobacterium tuberculosis*, *M. bovis*, *Salmonella* spp., *Listeria* spp., enteric viruses, *Brucella* spp., *Coxiella burnetii*, and *Campylobacter jejuni*.

Food-borne bacteria can cause serious diseases: *Salmonella typhi* causes typhoid fever; *Shigella* spp. cause bacillary dysentery; *E. coli* strains can cause dysentery; *M. tuberculosis* and *M. bovis* cause tuberculosis; *Vibrio cholerae* causes cholera; *Brucella* spp. cause undulant fever; and *Coxiella burnetii* causes Q fever. *Listeria monocytogenes* causes listeriosis in predisposed populations, for example, immune-compromised individuals. Hepatitis is caused by the Hepatitis A virus and the recently discovered Hepatitis E virus, which is common in Africa and India and other Asian countries, but not in Western countries. In meat and poultry products, *Salmonella*, *E. coli*, *Campylobacter jejuni*, *Listeria*, and *Clostridium perfringens* are the major pathogens. *Listeria monocytogenes* is the major cheese pathogen. Unlike other food-borne pathogens, its temperature growth range (from 31 to 122°F [–0.4 to 50°C]) allows it to grow under refrigeration conditions. Hepatitis viruses and *Yersinia enterocolitica* are major oyster pathogens. Some of the pathogens found on fish are of marine origin, for example, *Vibrio vulnificus*, *V. parahaemolyticus*, and *V. cholerae*, and others are from sewage, for example *Salmonella* spp. and *Campylobacter* spp. Nuts and grains can become contaminated with mycotoxins, aflatoxins produced by *Aspergillus flavus*, being the most dangerous.

Prions are particles, smaller than viruses, and mostly composed of protein. It has recently been proposed that prions are the cause of four diseases: Creutzfeldt-Jacob disease and kuru in humans, bovine spongiform encephalopathy (BSE or mad cow disease) in cows, and scrapie in sheep. It is now thought that several dozen people have gotten a human form of BSE by eating the meat of infected cattle. This disease has been named new variant Creutzfeldt-Jacob disease, or nvCJD.

**MICROORGANISMS.** Microorganisms are organisms (forms of life) requiring magnification to see and resolve their structures. "Microorganism" is a general term that becomes more understandable if it is divided into its principal types—bacteria, yeasts, molds, protozoa, algae, and rickettsia—predominantly unicellular microbes. Viruses are also included, although they cannot live or reproduce on their own. They are particles, not cells; they consist of deoxyribonucleic acid (DNA) or ribonucleic acid (RNA), but not both. Viruses invade living cells—bacteria, algae, fungi, protozoa, plants, and animals (including humans)—and use their hosts' metabolic and genetic machinery to produce thousands of new virus particles. Some viruses can transform normal cells to cancer cells. Rickettsias and chlamydiae are very small cells that can grow and multiply only inside other living cells. Although bacteria, actinomycetes, yeasts, and molds are cells that must be magnified in order to see them, when cultured on solid media that allow their growth and multiplication, they form visible colonies consisting of millions of cells.

Many people think of microorganisms mainly in terms of "germs" causing diseases, but some "germs" are beneficial to humans and the environment. Disease-causing (pathogenic) microorganisms need to be controlled, and in many cases, beneficial microorganisms are also controlled in plant and food production.

For thousands of years, people had no concept or knowledge of organisms invisible to the naked eye. In fact, it is only within the last several hundred years that magnification systems (lenses, magnifiers, microscopes) were developed that enabled scientists to observe microorganisms. In 1673 Antoni van Leeuwenhoek, a linen merchant in Delft in the Netherlands, was the first to observe and study microorganisms, using single lenses that magnified objects fifty to three hundred times. The role played by microorganisms was not clarified until the 1830s, when Theodor Schwann in Germany demonstrated that yeasts were responsible for alcohol production in beer and wine fermentations.

In 1854, Louis Pasteur in France found that spoilage of wines was due to microorganisms (bacteria) that convert sugars to lactic acid, rather than the alcohol produced by yeasts. He developed the process of "pasteurization," in which the temperature of food materials is raised to about 140 to 158°F (60 to 70°C), thereby killing many spoilage organisms. Pasteur also discovered that certain bacteria are responsible for the souring of milk. Today, milk is generally pasteurized to reduce its content of microorganisms, to extend its keeping quality, and to protect against pathogenic microorganisms that may be present.

Pasteur also discovered that each type of fermentation, as defined by the end products, is caused by specific microorganisms and requires certain conditions of acidity or alkalinity. He discovered further that some microorganisms, the aerobes, require oxygen and others, the anaerobes, grow only in the absence of oxygen. The latter probably developed in the earliest days of the earth when there was no oxygen in the atmosphere.

Microorganisms are present in high populations in soil, and in varying numbers in the air we breathe, the water we drink, and the food we eat; they are on our skin and in our noses, throats, mouths, intestinal tracts, and other bodily cavities. They are everywhere in our environment.

### Evolution of Microorganisms

Microorganisms came into being on earth over a period of about 1.2 to 1.5 billion years. Fossil microbes have been found in rocks 3.3 to 3.5 billion years old. Since then, microorganisms have had the principal task of recycling organic matter in the environment. As such they are absolutely essential to the health of the earth. Without them, the earth would be a gigantic, permanent waste dump.

Microorganisms are responsible for recycling the huge masses of organic matter synthesized by plants as

A microscopic view of *Salmonella*, the bacteria that contaminate food and cause widespread illness. COURTESY OF PHOTO RESEARCHERS, INC.

life on earth evolved. Furthermore, microorganisms—the cyanobacteria or their DNA in the chloroplasts in plant cells—were the source of most of the free oxygen in the early atmosphere. They also oxidize ammonia (the universal end product of protein metabolism) to nitrate, which is the only nitrogen source used by plants and is therefore essential for production of our plant foods. Microorganisms also are responsible for cellulose hydrolysis in the rumens (first stomach compartments) of cattle, facilitating the production of animal protein for human consumption. And, in recent times, microorganisms have been the sources of antibiotics that have enabled the cure of numerous diseases.

Blue-green algae (cyanobacteria) are prokaryotes (that is, their cells have no distinct nucleus). They are very independent nutritionally since they can perform photosynthesis using chlorophyll *a*. Thus they can synthesize sugars for energy from carbon dioxide using the sun's radiation. They also release oxygen. They can respire aerobically and can fix nitrogen, generating amino acids and protein. They require only water, nitrogen gas, oxygen, carbon dioxide, some minerals, and sunlight. The evidence is that they were on earth 3.2 billion years ago. The cyanobacteria are among the earliest microorganisms and very important even today.

Green algae are eukaryotes (that is, their cells have a distinct nucleus). They evolved about one billion years ago. They contain chlorophylls *a* and *b*, which enable them to convert carbon dioxide, through sunlight radiation, to sugars, and to polymerize sugars to starches, hemicelluloses, and celluloses—some of our most important sources of food energy.

Green algae are still major sources of food in the oceans. Green algae were likely the life forms that evolved into plants, which first lived primarily in the oceans but moved to the land about 450 million years ago, about the same time as the amphibians and first land animals

evolved. It is believed that the first mammals evolved about 150 million years later, along with insects and reptiles, which were dominant. Another 150 million years later, dinosaurs and the first birds evolved, along with the first flowering plants. During the entire period from 3.6 billion years ago, microorganisms were consuming and recycling the organic matter from themselves and other forms of life as they lived and died. For several billion years, bacteria, algae, and other microorganisms served as food for other microbes and for higher animals as they evolved. When plants evolved in the oceans and then subsequently moved to land, they became the major sources of food for other forms of life, including microorganisms, animals, and eventually humans.

### Evolution of Plants: The Basis for Human Foods and Animal Feeds

For at least 400 million years before humans appeared on earth, plants were producing food consisting of leaves, stems, seeds, nuts, berries, fruits, tubers, etc., that made life possible for humans and animals when they evolved. Early plant evolution was essential not only for food but also for producing an oxygen environment necessary for animal and human survival. Plants introduced a very effective way of using the sun's radiation to transform carbon dioxide into food materials, such as sugars, starches, and cellulose, through the green pigment chlorophyll and the organelle that serves as the site for photosynthesis, the chloroplast.

Both plants and animals evolved in a microbial environment, where the microbes were ready and able to recycle organic matter. Plants and animals had to develop ways of resisting microbial invasion. Plants did this in part by developing a lignocellulosic body resistant to microbial breakdown. Humans also evolved in a sea of microorganisms and have a tough skin over their bodies resistant to microbial invasion. They had to develop internal immune systems against invasion by microorganisms. Human blood contains phagocytes similar to and probably derived from free-living amoebas, which search out and consume invading bacteria. Then as now, some microorganisms could invade the live animal or human, causing disease.

Microbes enter our bodies in the air we breathe into our noses and lungs, into our mouths and throats, stomachs, and intestinal tracts via the water and foods we swallow, through our eye sockets, through our skin via abrasions and punctures, and through our genitals and other mucous membranes. This intimate contact with microbes begins at birth and continues through life. Some microorganisms become regular inhabitants, parasites of our bodies; they become what can be described as our normal flora. Some microorganisms are virulent, invading our bodies and upsetting our metabolic activities and causing disease; these are the pathogenic microbes. Other microbes are normal microbial flora or pathogens on

plants. Still other microbes are continuously invading plant food materials and recycling the organic matter. If this activity is controlled and stopped at the proper levels, these become our fermented foods, which include alcoholic foods and beverages; vinegars; lactic-acid-fermented cabbage and other vegetables (that is, sauerkraut and pickles); lactic-acid-fermented milks and cheeses; sourdough breads; Indian *idli* (from rice); Ethiopian *enjera* (a bread made from teff, an indigenous cereal grass); textured-vegetable-protein meat-substitutes, such as Indonesian tempeh (from soybeans or, sometimes, peanuts) and *ontjom* (from peanuts or, sometimes, soy fiber); high-salt meat-flavored amino acid/peptide soy sauces and pastes; African alkaline-fermented foods such as *dawadawa*, *soumbura*, and *iru* (all from locust beans [*Parkia biglobosa*] or soybeans); Indian *kenima*, Japanese *natto*, and Thai *thua-nao* (all from soybeans); and leavened yeast breads.

### Microorganisms Causing Food Poisoning

Three species of bacteria cause food poisoning via pre-formed toxin: *Clostridium botulinum*, *Staphylococcus aureus*, and *Bacillus cereus*.

*Clostridium botulinum* is a bacterium that grows in the absence of oxygen and produces one of the most toxic, deadly chemicals known to humans. It was first isolated from sausages, but later was responsible for death in persons consuming home-canned vegetables. The symptoms are flaccid paralysis eighteen to thirty-six hours after ingestion, with respiratory paralysis and death if untreated. There are antitoxins against botulinum toxin, if the type is identified and the antitoxin is injected in time. Botulinum toxin can be inactivated by heating the food to boiling for five minutes. Interestingly enough, botulinum toxin, in spite of its great toxicity is finding a use in eliminating lines and wrinkles from human skin by preventing activity of muscles directly involving those areas of the skin that have wrinkles or expressions. This is partially a response to the fact that very toxic substances in minute quantities can become stimulants.

A second serious type of food poisoning is caused by the ingestion of staphylococcal toxin produced by *Staphylococcus aureus* in foods such as cream puffs, mayonnaise, ice cream, or other nutritious foods that become infected with staphylococci, often carried in the nasal secretions of food handlers. Staphylococcal toxin causes a rather violent nausea and vomiting thirty minutes to six hours after consuming food contaminated with the toxin. *Staphylococcus* toxin is not inactivated by boiling. It generally is not fatal.

*Bacillus cereus* also produces a food-poisoning toxin. Steamed rice held overnight at room temperature has been a typical food causing *Bacillus cereus* poisoning. There are two toxins involved—one causing nausea and vomiting, the other causing diarrhea. The toxins are not inactivated by boiling.

### Microorganisms Producing Food Poisoning by Toxins Formed in the Intestinal Tract

*Clostridium perfringens*, an anaerobic microorganism that can cause gangrene in wounds, can also cause food poisoning if it overgrows food materials, such as gravies and meats, which are then consumed. It produces its toxin in the intestinal tract of the consumer and causes diarrhea.

*Vibrio cholerae* is a major cause of cholera in man; it is spread via contaminated water and food. The symptoms are profuse diarrhea, which, if not treated to replace fluids in the body, will lead to death. *Vibrio parahaemolyticus*, found in contaminated shellfish, also leads to profuse diarrhea and requires fluid replacement and antibiotics.

Shiga toxin-producing *Escherichia coli* (STEC), found in contaminated water and meats such as hamburger, is a serious food pathogen leading to hemorrhagic colitis (diarrhea with blood). Bovine products are a major source, but lettuce, alfalfa sprouts, and apple cider have also been implicated.

Enterotoxigenic *E. coli* (ETEC) is frequently found in developing countries in contaminated water and food and is associated with travelers' diarrhea (diarrhea without blood).

### Food-Borne Bacteria Invading Intestinal Epithelial Cells

Common causes of food-borne illness are salmonella bacteria. *Salmonella typhi* and *Salmonella paratyphi*, gram negative bacilli that invade the intestinal epithelial cells, cause typhoid and paratyphoid fever, respectively. They are generally found in water or food contaminated with fecal material from carriers of salmonella. Other salmonellae are carried by infected poultry meats and eggs.

*Campylobacter* spp. are now recognized as one of the most common causes of food gastroenteritis. Main vehicles are raw meats (especially poultry), milk, and water. Fever (sometimes high), headache, and myalgia (muscle pain) precede nausea, vomiting, and diarrhea. *Yersinia* spp., carried chiefly in undercooked pork but sometimes also in milk, is another serious food-borne infection.

*Listeria monocytogenes* is the cause of a food-borne disease that is frightening because of its high mortality (fatality is over twenty percent). Among incriminated foods are milk, cheese, raw vegetables, and undercooked meat, including frankfurters.

Viral food-borne pathogens include hepatitis A, hepatitis E, rotavirus, and Norwalk virus. Although these viruses do not reproduce in food or water, they are spread by contaminated human carriers and food handlers through such media.

### Fermented Foods

Seeds for plants germinate in the soil surrounded and covered with microorganisms. A pinch of dirt can contain a billion microorganisms of many types. The plants

destined as foods for humans and animals grow in soil surrounded and covered with microorganisms ready to invade any organic matter and recycle it (essentially consume the organic matter and return it to compost utilizable by new seeds and plants). When the plant materials—seeds, nuts, leaves, tubers, stems, roots—are harvested, they are contaminated or infected with the types of microbes present in the soil; the microbes immediately start to grow on any susceptible organic matter that is available, as long as there is sufficient moisture to allow growth. Dry seeds and leaves are resistant to overgrowth by microorganisms, but as soon as they absorb enough moisture, they become susceptible to microbial growth. If the products of the microbial growth have desirable or attractive aromas and flavors and if they are nontoxic and do not cause disease when consumed, they can be described as “fermented foods” and can become an accepted food in the diet. If they have unpleasant aromas or bad flavors or if they cause food poisoning or death when consumed, they are considered to be spoiled and become garbage on their way to compost or soil. From the earliest times, our food supply has been strongly affected by fermentation.

**Alcoholic beverages.** The earliest sweet food on earth was likely honey, produced by honeybees and stored for their future use. Humans, in competition with animals such as bears, have always striven to collect honey for their own consumption. Honey is very resistant to spoilage in its concentrated form (about eighty percent sugars), but if it is collected and stored in a container and becomes diluted by rain water, yeasts present in the environment ferment the sugar in the honey to ethyl alcohol (ethanol). The products are called mead or honey wine, one of the earliest alcoholic beverages known to humans and still consumed today.

Similarly when humans started collecting sweet fruits and berries in containers, the juices as well as the fruits and berries themselves were quickly invaded by yeasts on the surfaces of the fruits that ferment the sugars to alcohol (actually a step in recycling), producing a primitive wine. For better or worse, humans have prized alcoholic beverages and they are still consumed in large quantities throughout the world except in those populations that avoid alcohol because of religious restrictions. In some religions, wines are a component of the religious services. Humans discovered ways of producing other alcoholic beverages. For example, early man probably discovered that chewed corn when mixed with water and stored in a container produces an alcoholic beverage. The process occurs because saliva contains an enzyme, diastase, that converts starch in the corn to sugars; then yeasts in the environment ferment the sugars to alcohol. The beverage thus produced is called *chicha* in the Andes region of South America. In ancient times, an emperor in that region could hold office only as long as he delivered sufficient *chicha* to the citizens to keep them happy. Even today, among families in the Andes region, husbands will

get drunk one weekend and wives will get drunk the next, ensuring that at least one parent is sober and able to look after the children.

Juices from palm trees are collected by cutting the flowers and allowing the sap to flow through bamboo tubes into a container. As the juices flow through the tubes, they become infected with yeasts and other microorganisms. The sugars are fermented to alcohol and the product, palm wine, is produced in large quantities in the tropics. It is very rich in vitamins valuable to the consumer.

When cereal grains such as rice, barley, wheat, and corn are collected and soaked, or if they become wet from rain, they start to germinate, and starch in the seeds is changed to fermentable sugars that are fermented by yeasts in the environment, yielding an alcoholic beer. It has been suggested by anthropologists that this process was an early cause of fundamental social change. To ensure the continuity of supply of fermentable sugars, people settled in permanent locations. Agriculture, in turn, was a way of ensuring the regularity of production of fermentable cereal grains.

Alcoholic beverages are major fermented foods in the diet of humans. The yeast fermentation not only leads to a highly accepted beverage, it is a safe method of preserving fruit and berry juices until they can be consumed. The yeasts also enrich the beverages with B-vitamins.

As long as the wine or beer is kept anaerobic (air is excluded), it is preserved, but if there is access to air, there is a second fermentation by bacteria (*Acetobacter*) in the environment that transforms the alcohol to acetic acid (vinegar), which is even more preservative than ethyl alcohol. Many primitive wines and beers contain both alcohol and acetic acid. The vinegar fermentation is an ancient process that is still very important today. Vinegar is used to preserve cucumbers and other vegetables as pickles, which make an important contribution to the food supply of people around the world.

**Milk products.** As soon as humans started milking cows, they found that milk held a few hours at room temperature became sour. They did not know why, but it was, in fact, the streptococci and lactobacilli in the environment that produce lactic acid from lactose in the milk. This is the basis for yogurts, and the souring process as practiced in the early days also led to the development of cheeses.

The principal early milks were those from sheep or goats. Milk was often collected and stored in animal stomachs or hides, which allowed for the souring process to occur, the butter to be removed, and the milk curds to accumulate. The skin of a sheep or goat was carefully removed undamaged. The openings of the limbs and neck and the natural openings were tied. The hair was removed and the skin bag was used to collect the milk. During souring, the curds separate from the whey. The curds

gradually lose moisture through the porous container, and further microbial activity and chemical changes lead to a primitive cheese. Today there are more than three hundred types of milk cheeses available. They have a wide range of flavors and textures and add variety and high-quality nutrition to the diets of consumers.

In addition to the bacterial cheeses, fungal cheeses involving growth of *Penicillium roqueforti* (Roquefort cheese and blue cheese) and *Penicillium camemberti* (Camembert cheese) on or in the cheese curd led to new flavors and textures for this class of fermented foods.

The Chinese developed a cheese from soybean milk, called *sufu*. Soybeans are soaked, ground with water, filtered to obtain the fluid milk, and heated to near boiling, and the curd is precipitated with calcium or magnesium salts. The filtered and pressed curd is then inoculated and becomes overgrown with *Mucor* spp. mold, after which it is aged in a salt and alcoholic brine. It is then ready for consumption.

**Lactic-acid fermentations.** An ancient food-fermentation technique is found in the South Pacific, where islanders centuries ago discovered that foods such as cassava, plantains, and bananas could be preserved for long times by piercing them and packing them in pits that were sealed against oxygen entry. Lactobacilli, *Leuconostocs*, and streptococci ferment sugars in the stored food materials to lactic acid, acidifying them and preserving the food against spoilage as long as the pits remain sealed. Pits opened after one hundred years of storage have revealed edible products—the result of bacterial fermentation.

In Ethiopia, pulp of the false banana, a starchy paste, is similarly stored in pits and undergoes lactic-acid fermentation, preserving the starch, which serves as a base for bread. Lactic-acid fermentations of cabbage—for example, sauerkraut and Korean kimchi (which is based upon Chinese cabbage, radishes, and red pepper)—are important processes around the world. Sauerkraut and kimchi are particularly interesting applications of bacterial fermentation. The cabbage is shredded and two to three percent common salt is added. The salt extracts nutrients from the cabbage and a series of bacterial species (*Leuconostoc*, *Lactobacillus*, *Pediococcus*) overgrow the cabbage, producing lactic acid and carbon dioxide that preserve the cabbage; and as long as the product is kept anaerobic, it remains preserved.

Soybeans, with a content of about twenty percent fat and forty percent protein, are a very nutritious food source, first cultivated in Asia. They are harvested dry and have an excellent keeping quality. However, if they are moistened or soaked in water, they become susceptible to overgrowth by bacteria that first acidify them. Then they may be boiled, as in preparation for eating. After this, they become susceptible to overgrowth by molds. In Korea and northern China, the average tem-

perature is cool, below 86°F (30°C), and the moistened soybeans become overgrown by *Aspergillus oryzae*, a mold that is present in the environment, particularly on the soybean straw. If such soybeans are stored under the roof, as is commonly practiced, the soybeans first become white from the mold mycelium (a mass of filamentous growth). Then they become green from the mold spores. During this time, the mold is producing many kinds of digestive enzymes. If such mold-covered soybeans are then mixed with water and salt to form a paste, it will be found that the paste has a meatlike flavor because of the amino acids and peptides released by the mold as it digests the soybean proteins. The end product of this process, called miso in Japan and *chiang* (soybean paste) in China, is used extensively as an ingredient for soup. If the mold-covered soybeans are placed in salt water, especially concentrated salt brine, it is found that the soybeans, which are initially bland in flavor, become meat-flavored, as in the miso process. The product, when filtered, is soy sauce. Today, soy sauces are used to season and marinate foods, not only in Asia but around the world.

Soybeans are also used in Southeast Asia—in Indonesia, Malaysia, and Vietnam. However, the average temperature is generally higher, about 90 to 100°F (32 to 38°C). *Aspergillus* molds grow optimally at about 77 to 86°F (25 to 38°C), so they tend to invade the soybeans in North Asia. In Southeast Asia, other molds such as *Rhizopus oryzae* and *Mucor* spp. grow faster and better at the higher temperature. Thus the environment becomes infected with spores of these molds. When soybeans are soaked or moistened in Southeast Asia and are then cooked and cooled, they become overgrown with molds of the *Rhizopus* or *Mucor* types. If allowed to digest as a paste or in salt brine, they also can lead to a soy-sauce or miso flavor, but the Indonesians and Malaysians allow the mold-covered soybeans to become knitted into a cake that can be sliced and deep-fat fried or used in soups as a substitute for meat, which is generally in short supply in the diet. The product is called *tempeh kedele* when made from soybeans. The Indonesians have developed other products using peanut and coconut press cakes (from the production of oil) as substrates. The pulverized, soaked press cakes are re-formed into cakes and steamed. They then become overgrown with *Rhizopus* or *Neurospora* molds to produce foods called *ontjom* (peanut) and *bongkre* (coconut) that like tempeh have a texture that allows them to be sliced and used as a substitute for meat in soups.

Fermented foods have been consumed by humans for centuries and are generally safe, but it should be cautioned that some molds produce toxic, even carcinogenic, products (for example, aflatoxins) and should not be consumed.

There are numerous other fermented foods that utilize edible microorganisms in their production and add variety and nutritive value to our diets.

## The Role of Microorganisms in Soil

Plant life, our basic food supply, is dependent upon the trillions and trillions of microbes that exist in the soil, degrading organic matter, recycling nitrogen and carbon, and producing new soil in forms plants can use directly. Thus, good soil, far from being dead, should be described as "living soil," because of its content of living microorganisms. In fact, the rhizosphere, the area surrounding the roots of most plants, contains a wide variety of microorganisms that help the plant to absorb minerals and other plant nutrients. Some plants, such as legumes, have nodules on their roots that contain nitrogen-fixing bacteria, which take nitrogen from the air and produce nitrogen compounds the plants use in the synthesis of amino acids and protein; these are an important protein source in the human diet.

## Microorganisms as Food

Blue-green algae of the genus *Spirulina* have been harvested from ponds and eaten for centuries by the ancient Aztecs in Mexico and Africans in the region of Lake Chad.

Mushrooms, the fruiting bodies of microorganisms that live on decaying lignocellulosic compounds in soil, are highly prized as food by nearly all human societies, as well as by many animals, including insects.

Fermentation plays several roles: (1) enrichment of the human diet through development of a wide diversity of flavors, aromas, and textures in food; (2) preservation of substantial amounts of food through lactic acid, alcoholic, acetic acid, and alkaline fermentations; (3) enrichment of food substrates biologically with protein, essential amino acids, essential fatty acids, and vitamins. Protein content is often increased, as for example in Malaysian *tape ketan* and *tape ketella* by utilization of the carbohydrates, lowering their percentage and raising the percentage of protein in the food. Protein quality is also increased by the synthesis of essential amino acids such as lysine, first limiting amino acid in rice. In the Malaysian *tape* fermentation the content of lysine is raised, improving its protein quality. In the Indian *idli* fermentation, it has been reported that methionine, the first limiting amino acid in many legumes, is increased from 10.6 to 60 percent. Highly polished rice is deficient in thiamine (vitamin B<sub>1</sub>), and consumption can lead to beriberi, a disease characterized by muscular weakness. In the Malaysian *tape* fermentation, thiamine content is raised to that of the original unpolished rice. In the Indonesian *tempeh* fermentation the content of riboflavin doubles, niacin increases seven-fold, and vitamin B<sub>12</sub>, which generally absent in vegetarian foods, is synthesized. In the African kafir beer fermentation, riboflavin doubles and niacin/nicotinic acid concentration nearly doubles. Mexican *pulque*, the oldest alcoholic beverage on the American continent, contains thiamine, riboflavin, niacin, pantothenic acid, pyridoxine, and biotin that are of particular importance to the low income children of Mexico.

There is much hunger, starvation, and malnutrition in parts of the world today, and the world population is predicted to reach eight to twelve billion by the year 2050. As world population increases, the supply of meat and other animal products available per person is likely to decrease. A large, capable research institute in England has developed a process in which edible mold mycelium is grown and used to provide protein and texture for meat analogues (substitutes) for the human diet. Microbial protein can also be extracted from cells, and then concentrated, isolated, and spun or extruded to make meat substitutes.

Although this would appear to be very advanced technology, the Indonesians for centuries have overgrown soaked, partially cooked soybean cotyledons with the mold *Rhizopus oligosporus* (as mentioned above), which knits the soybean cotyledons into a firm cake that can be sliced and deep-fat fried or used in chunks as a substitute for meat in soups. The protein content rivals that of meat and the cost is very low, within the means of the average Indonesian. Also, the microorganisms involved enrich the food with vitamin B<sub>12</sub>, increase niacin by a factor of seven, and double the riboflavin content.

Among plants, the grasses are the most efficient fixers and utilizers of carbon dioxide, producing sugars, starches, and cellulose; they are also synthesizers of protein, using nitrogen from the soil. Grasses can double their cell-mass in two to three weeks. A 1000 kg harvest of grass can be repeated every two to three weeks. However, yeasts are much more efficient in this regard. A yeast (1000 kg) grown in tanks on limited land space can produce 168,000 kg of cells containing 84,000 kg of protein every two weeks.

Bacteria are even more efficient: whereas yeasts can double their cell mass in about two hours, some bacteria can double their cell mass in twenty minutes. Still, 1000 kg of yeast growing in a suitable fermentor can produce 1000 kg of new cells for harvesting every two hours, with a daily production of 12,000 kg of cells containing 50 percent or 6000 kg of protein. (Molds generally grow more slowly, doubling their cell mass in four to six hours.) Since the protein content of bacterial cells may reach 80 percent (compared with 40 to 45 percent in soybeans, for example), there is no method of producing protein that can compete with microbial cells. Except for algae, microbes require energy sources such as sugars, starches, cellulose, or hydrocarbons—all derived originally from the sun's radiation. But they can utilize energy sources that humans cannot digest, such as cellulose and lignocellulose found in straw. As described earlier, mushrooms are a good example of such microorganisms: they produce delicious, edible food directly from straw and sugarcane bagasse.

Only about twenty-five species of more than two thousand edible fungi are widely accepted as human food. The four most important mushrooms are the commonly

cultivated white mushroom or button mushroom (*Agaricus campestris*), the black forest mushroom shiitake (*Lentinus edodes*), the straw mushroom (*Volvariella volvacea*), and the oyster mushroom (*Pleurotus ostreatus*).

Mushrooms can be grown on a wide variety of inexpensive, inedible substrates such as cereal straws, sugarcane bagasse, banana leaves, sawdust, cotton wastes, and animal manure. World production of straw is estimated to be about two billion tons. One kg of dry straw compost material can yield one kg of fresh mushrooms. Thus, straw, if all were used for production of mushrooms worldwide, could provide eight billion consumers with 250 grams of fresh mushrooms daily. Mushrooms are high in essential amino acids and nutritional value. They also appeal to almost all consumers for their flavors and flavor-enhancing capabilities. Mushrooms, a microbial product, are thus likely to play an important role in feeding the world in the future. And straw, after serving as a substrate for mushroom production, is nutritionally superior to raw straw for feeding cattle. The straw has been partially recycled and made more digestible in the process.

As world population rises in the twenty-first century, microbes may be used to a much greater extent to feed mankind, or at least feed animals that, in turn, will yield meat for the human diet. Humans, plants, and animals have been intimately involved with microorganisms ever since they evolved. While some of the microorganisms cause serious diseases, there are also many that provide foods and feeds and are beneficial to other life on earth.

**MICROWAVE OVEN.** While experimenting with radar during World War II, Percy Spencer of Raytheon Corporation in Waltham, Massachusetts, discovered the heating properties of microwaves. With a candy bar in his pocket, he leaned in front of the microwave tube and the candy bar promptly melted. This event led to the birth of microwave ovens.

In 1945 Spencer submitted his first patent application for heating food with microwaves. The patent described two parallel magnetrons that heat food that passes by on a conveyor belt. Two years later, William M. Hall and Fritz A. Gross, Spencer's co-workers, applied for a patent for a microwave-heating device enclosed in an oven. This device consisted of two microwave-generating magnetron tubes packed in a metallic box. The oven included a timer and a means of controlling power.

Raytheon's president, Laurence Marshall, was interested in Spencer's patent. A prototype microwave oven was constructed in 1946 costing an estimated \$100,000. Marshall was also enthusiastic about the prototype and ordered engineers to develop an oven in which cold sandwiches could be heated. A contest was held to name the new oven—the winner was "Radarange."

#### Commercial Microwaves

The first commercial Radarange model was a freestanding white-enamel unit operating at 220 volts of electricity and with an internal water-cooling system. The first Raytheon microwave oven was sold to a restaurant in Cleveland, Ohio, in 1947. Subsequent Radaranges incorporated sliding vertical doors. With a price tag of \$3,000, sales were mainly limited to restaurants, railroads, cruise ships, and vending-machine companies.

Development of the microwave oven continued during the 1950s. Raytheon dominated the field of commercial microwave ovens and heating applications: It was the only manufacturer of ovens for restaurants and was the principal magnetron manufacturer. Raytheon licensed other companies, such as Hotpoint, Westinghouse, Kelvinator, Whirlpool, and Tappan, to manufacture the ovens. Raytheon furnished power supplies, magnetrons, and basic-oven design data to each company. The Tappan Company began experimenting with a Radarange installed in their lab. Tappan engineers, who

were experts in cooking, teamed up with the Raytheon microwave engineers. In January 1952 the Tappan Company developed the first domestic commercial Radarange. It was powered by a 1,400- to 1,700-watt magnetron that was water cooled and required plumbing connections. The unit was five and a half feet high and weighed 750 pounds.

### Domestic Microwaves

The experimental unit developed by Tappan was impractical for domestic use. What was needed was a magnetron requiring less power and a heat dislocation system that could replace the water cooling mechanism. Tappan engineers designed a cabinet with an air-cooled system. Eventually, the magnetron and related components, which had fed microwaves directly into the cavity, were relocated behind the oven. In October 1955, Tappan introduced the first domestic microwave oven for the consumer market. Designed to fit a standard forty-inch range or for built-in use, the unit had a stainless-steel exterior and aluminum oven cavity with a glass shelf. The oven featured two cooking speeds (500 or 800 watts), a browning element, timer, and a recipe-card file drawer. It retailed for \$1,295. The unit was marketed as an "electric range." Its advertised advantages were cooking speed, a cool oven, and a unique reheating capability.

General Electric's Hotpoint division, which also had been researching microwave cooking, unveiled its electronic oven the following year. Both the Tappan and Hotpoint oven generated unprecedented enthusiasm and interest in 1956, but sales were dismal. The price was high for the average consumer, and food-processing techniques for the microwave were not well understood. Few food processors took the technology seriously, thus few microwaveable foods were produced.

### Breakthroughs

Tappan continued to improve its product. By 1965 Tappan had introduced the first "microwave cooking center," which consisted of a microwave oven mounted above a conventional range. This unit still retailed for well over \$1,000. Despite these advances, only ten thousand households in the United States owned microwaves by 1966.

Two events revolutionized the microwave industry. The first was the invention by Keisha Ogura of the New Japan Radio Company—40 percent of which was owned by Raytheon—of a compact, low-cost magnetron. The second was Raytheon's acquisition of Amana Refrigeration, Inc. George Forestner, Amana's president, was a microwave visionary. Amana appliance engineers teamed up with Raytheon experts to develop and design a household Radarange. In August 1967, Amana released its first microwave oven, the Amana RR-1. It operated at 115 volts and sold for \$495. The unit was well received. The Amana RR-1 set off a revolution in microwave oven technology, and Amana's success encouraged other appliance manufacturers to produce microwave ovens.

Another important microwave oven manufacturer was Litton, which acquired a small microwave manufacturer called Heat & Eat in 1964. Previously, Litton had manufactured commercial microwave ovens for restaurants. Its newly named Microwave Cooking Products Division in Minneapolis targeted the home market. Litton's Model 500 used 115 volts and was compact. These ovens were installed on TWA planes in 1965, and Litton dominated the restaurant business by 1970.

### Microwave Challenges

Despite the initial successes, there were still problems to overcome before the microwave oven would be generally accepted. Manufacturers needed to convince the public that microwave ovens were safe. This fear began with the U.S. Congress's passage of the Radiation Control for Health and Safety Act in 1968. On 4 January 1970, the U.S. Department of Health, Education, and Welfare published the results of microwave oven radiation tests. The tests showed that microwave ovens leaked microwaves. Thus the federal government developed new standards and required changes in the construction of ovens beginning on 6 October 1971. These new regulations required design changes that would result in safer microwave ovens. Public apprehension slowly abated.

Another crucial challenge was convincing food processors to repackage their products. Foods packed in foil blocked microwaves and damaged ovens. Also, frozen foods contained too much water for microwave use. At first, food processors were not interested in working with microwave manufacturers. By the 1970s, however, more than 10 percent of all U.S. homes possessed microwaves, many microwave ovens were in use in vending businesses, and numbers were steadily increasing. Major food processors quickly reversed their direction and invested in microwaveable food products, and specialized microwave cookware was introduced. By 1975 microwave ovens outsold gas ranges, with sales of over one million units. In the early twenty-first century, the primary use of microwave ovens in the United States was to reheat food.

**MIDDLE AGES, EUROPEAN.** To understand medieval cuisine, we have to start with Roman culinary practice, which probably kept its influence long after the decline of the Roman Empire. Two ingredients were of particular importance here: the liquid salt called *garum* or *liquamen* and the granular gum *asa foetida* or *laser Parthicum*. *Liquamen* or *garum* was the liquid salt of Roman high cuisine; it was usually made not by the cooks themselves but in factories, notably in Pompeii. For this purpose a vessel holding about thirty liters was filled with layers of fish, salt, and dried herbs, and then covered. This mixture stayed in the sun for a week and was then stirred well daily for twenty days until the fish and herbs were fully pulverized by fermentation and blended into a liquid. This was strained and sold in amphorae. Often it was combined with olive oil and wine, sometimes with honey or sweet wine and with pepper, lovage, and sweet marjoram as well. Some of the herbs for the *garum* were dill, coriander, fennel, celery, savory, sage, rue, mint, lovage, thyme, and sweet marjoram. These herbs are available today in dried or fresh form, and we can more or less imitate the *garum* ourselves. We also can make use of a Vietnamese product, called *nuoc mam*, which is prepared in the same way and has the same function. The advantage of liquid salt in comparison with solid salt is that the liquid keeps the meat succulent, whereas the solid salt extracts the juices.

The Romans also made a cheaper version with fewer herbs by not putting the fish, salt, and herbs in the sun for fermentation, but boiling them for a short time. In this way, the fish quickly becomes pulverized and releases its liquid, which, depending on the quality of the bones, tends to become a jelly. Just before this happens, the liquid is strained and kept as a substitute for *garum*. The Romans called this salty juice *allec*, which in the Middle Ages became the word for (salted) herring.

Besides *garum*, the Romans used another favorite product now called *asa foetida*. This gum, derived from the roots of a Near Eastern umbellifer, not only smells bad but also tastes bad; nevertheless, it seems to have been consumed lavishly by the Romans. Originally, the Romans had used not this plant, which they called *laser Parthicum*, but the *silphium* or *laserpicium* from North Africa, a plant they consumed so recklessly that it was nearly extinct at the beginning of our era. The Romans then started to import *laser Parthicum*, which is called “ferula asafetida” by modern pharmacists, as a substitute. In large quantities it is hardly digestible for our stomachs and soon gives one a feeling of satiation and even nausea, but in small quantities it is not disagreeable.

From these two products, *liquamen* or *garum* and *asa foetida*, we may conclude a lot about the taste preferences of the Romans: savory with herbs from the Mediterranean region, which were grown partly in their own gardens. They favored East Asian spices like ginger and cardamom much less, although these were well known. Only the peppers, both black and white, were commonly

used. As for sweeteners, sugar was still unknown; it was not imported from Ceylon and Asia Minor until the seventh century. Sugar cane was grown by the Arabs in Sicily starting in the tenth century, but it was only after the Crusades that it found its way to Europe as a very expensive kind of spice. Instead of sugar, the Romans used honey or reduced wine (*defrutum*) and raisins, dates, and figs. For the rest, their victuals consisted of fish, fowl, a bit of pork, beef, or mutton, many legumes such as chickpeas and lentils, fruits, vegetables, olive oil, eggs, cheese, and various kinds of grain.

Pasta already existed, if we may translate the word *tracta* this way; however, it was not pasta in strands like spaghetti but in sheets like lasagna. These were used as dividers between wet fillings to make layers within a pie. The very thin, round sheets, called *tracta*, were rubbed between the fingers and used as a binding agent for stews, a practice which survives as *Reible* in South German cooking.

### The Early Middle Ages

How long this kind of nourishment held the stage in Western Europe during the Middle Ages is hard to say because detailed information is lacking. We can only conclude that there must have been a certain continuity in the taste for herbs and spices, at least until the Carolingian era of the ninth century. This can be deduced from a 716 charter of the Merovingian king Chilperic II for the abbey of Corbie in Northern France that was, in turn, a confirmation of a charter of King Chlotar III from the third quarter of the seventh century. In the charter, freedom from duties at the toll in Fos near Marseilles was granted for the following imported foodstuffs: olive oil, *garum*, pepper, cumin, cloves, cinnamon, spikenard, *costum* (an aromatic root from India), dates, figs, almonds, olives, peas, and rice. So *garum* was still in use in that period together with a few Indian spices, but *asa foetida* is no longer mentioned.

Not only some of the spices, but also the garden herbs must have remained in favor, judging from the last chapter of the *Capitulare de Villis* (Ordinance in chapters about the demesnes) of Charlemagne, in which the cultivation of about seventy kinds of herbs and vegetables in the gardens of every demesne in his empire was enumerated. There we find most of the herbs needed for the making of *garum*, as well as several other plants like beans, peas, onions, chives and garlic, cucumbers, watermelons, gourds, beets, endive, and lettuce, as well as fruit trees. The Carolingian population could be assured of a healthy diet if it lived according to the prescriptions of Charlemagne.

The same holds true for the monks at St. Gall in Switzerland, provided that they actually grew and used all the plants that are shown on the map of their monastery from about 817. There we find three gardens with edible plants: the *bortus* or vegetable garden, the *herbularius* or herb garden, and the orchard. The species, however, were not strictly separated, for in the *bortus* there were

not only vegetables like onions, garlic, leeks, celery, beets, black radishes, lettuce, parsnips, and cabbage, but also herbs like coriander, dill, parsley, chervil, and savory, and, for medical use, poppy and corn-cockle. In the *herbularius* we not only find roses, lilies, and iris, but also beans, next to herbs like savory, costmary, goat's horn, rosemary, peppermint and water-mint, sage, rue, cumin, lovage, and fennel. In the orchard we come across apple, pear, prune, mountain ash, quince, medlar, fig, chestnut, peach, hazelnut, walnut, almond, mulberry, and bay.

Monks were allowed to eat vegetables and fruits, for the Rule of St. Benedict states that at every meal, fresh vegetable or fruit, when available, were to be served in addition to two cooked dishes (which were probably made of fish, dairy products, and grains). Walafrid Strabo, ninth-century abbot of the Benedictine monastery at Reichenau on Lake Constance in Switzerland, celebrated in his poem "De cultura hortorum" (About the cultivation of gardens) the plants in his abbey's garden, such as sage, rue, lemon herb, gourd, water-melon, fennel, lovage, chervil, mint, celery, catnip, and black radish, along with poppy, rose, lily, and iris. For the most part we find these plants as well in the *Capitulare de villis* and on the map of St. Gall, from which we may conclude that they were widespread in the Carolingian period. But recipes for preparing them are not known, and nothing can be said about the refinement of the dishes served. The same holds true for the eleventh-century food prescriptions from the abbey of Werden on the Ruhr River in Germany, according to which the monks alternately had fish, cheese, and eggs, or cheese with vegetables for dinner, with wine and ale for drinks and mead on Sundays.

It must have been possible to compose quite delicate menus with simple ingredients that were permissible for the monks; this is indicated by the ironic words of Bernard of Clairvaux in 1124 in his *Apologia ad Guillelmum* (Apology to the Abbot William [of Saint Thierry near Reims]) about the eating habits of the abbey of Cluny in Burgundy. In this treatise he ridiculed the many ways of preparing a simple ingredient like eggs and reproached the abbot for the manner of serving one dish after another when the stomach had already been fully satisfied, but the eye remained curious about new colors and shapes. In this way, he condemned exactly those characteristics that would later become the glory of French cuisine, especially the refined sequence of the courses, in which the former dishes did not give a feeling of satiation but on the contrary stimulated the appetite for the latter ones.

### The Later Middle Ages

In the meantime, however, this refined sequence of courses was far from common if we judge from the existing menus of the meals of princes and other nobles in the later Middle Ages. These menus contained in England in the fourteenth and fifteenth centuries no more than two or three courses—each course, however, con-

sisting of at least ten dishes without any specific sequence of sweet, savory, sour and sharp, fish or fowl or meat, boiled, baked or roasted. In France the dishes at a festive dinner were divided among five or six courses, but there was also no fixed sequence like that of later ages. A common feature of aristocratic foodways all over Europe was the accent on meat, fowl, and fish (sometimes game, although less than one would expect), in contrast to the rather vegetarian eating habits of former centuries.

It is possible to study late-medieval recipes and to imitate them more or less exactly. By the late Middle Ages, tastes had changed rather drastically from those of the Carolingian period; new spices from East Asia with vinegar or sour grape juice, called *vertjus*, had taken over the role of primary seasonings, replacing the many herbs and vegetables with *garum* that had been favored earlier. Parsley, savory, sage, and hyssop were still used, but other herbs had become rare. Salt, when it was used at all, was added after cooking. This was due not to the presumed expensiveness of salt—the Asiatic spices were much more expensive—nor to the fact that much salted fish and meat was used, but probably to the dominant role of spices like ginger, cinnamon, cloves, mace, nutmeg, galingale, cardamom, and pepper. These ingredients provide enough flavor that the absence of salt is not noticeable, even in dishes that are prepared with fresh meat, game, fish, or fowl.

In this context, another critical point must be made. We sometimes hear or read that people in the Middle Ages needed so many sharp spices because their meat was always spoiled, and they had to hide the bad smell and taste. But although their means of controlling the quality of their food was less elaborate than in the modern Western world, it is nonsense to pretend that they were always balanced on the edge of food poisoning and tried to conceal this with heavy seasonings. They certainly had other medical conceptions than today, but in practice they understood very well how to combine these theories with wisdom gained from long experience. People knew quite well what was healthy and what was not and were on their guard not only against really spoiled meat but also against unsafe water: instead of water, they used wine or broth or boiling liquid from peas (*purée de pois*) in the kitchen. They drank beer and ale in Northern Europe, wine in Southern Europe, and cider in a narrow strip from England to Normandy and Brittany. So the difference in our eating habits is not in the lack of hygiene, but in the fact that they dined less frequently but in bigger quantities with more calories at the same time, and, in the case of the strict rules and regulations in the monasteries, no more than twice a day.

The change in taste after the Carolingian era was caused not by the consumption of half-spoiled meat or fish, but by other factors, largely economic ones. The merchants of the tenth and eleventh centuries had a keen eye for the fact that the small ships and simple harbor equipment of their time meant that the best gains were

to be expected from articles that took little space and at the same time were very expensive because they were rare. The Asian spices fit these requirements exactly. They were transported through Asia along land routes and brought to the Levantine harbors of the Mediterranean, and then taken by Venetian ships to Italy. From there they were traded along rivers and land routes to the North, where in the fairs of Champagne in France there were middlemen who exchanged the spices for the products of Flanders and Scandinavia, such as woolen cloth and timber.

Included were not only the spices that had been known and favored in antiquity, such as pepper, ginger, and cardamom, but also cinnamon, nutmeg, mace, cloves, and galingale. Added to these was an article from Asia Minor and the Balkans that was and still is even more expensive than the Asiatic spices—saffron, the dark-yellow stigmas of the stamen of the *Crocus sativus*. In antiquity, saffron was mainly used as a dye and a medicinal drug, but in the Middle Ages it became obligatory in high cuisine and primarily served the purpose of coloring the food yellow. Pure, genuine saffron was as expensive as gold. Adulteration of the stigmas, mainly in the shape of powder and mixed with other yellow stuff had already been the nightmare of physicians in antiquity and was punished with heavy fines or mutilation.

### Fasting Prescriptions

Colors played an important role in medieval cookery because the cooks not only tried to make dishes as attractive as possible, but also very often to disguise their real nature. This tendency was connected with the impediments the Christian Church imposed on the foodways with strict rules about fasting and abstinence. People had to abstain two days a week—for example, Wednesday and Friday, or Friday and Saturday—from the meat of quadrupeds. However, fish and other aquatic animals were permitted on those days, as were chicken eggs and dairy products. During some periods of the year, however, not only the meat, but also the milk, butter, and cheese of quadrupeds were forbidden, together with fowl and its eggs. Only fish, snails, and aquatics like mussels and oysters remained outside these prescriptions: they were always allowed as long as they were not prepared with butter or lard.

There were periods of the year in which not only a two-days-a-week abstinence but a full fast was ordered; this meant that dairy products and eggs, in addition to meat, were forbidden. The most important of these periods was the forty days of Lent from Ash Wednesday to Easter (not including Sundays, which were never fast days). The so-called Ember days were also a time of fasting. These days, whose name is a corruption of *quatuor tempora* (four seasons), coincided more or less with the change of the seasons. They were the Wednesday, Friday, and Saturday following the Feast of Saint Lucia (December 13), Ash Wednesday, Whitsunday (Pentecost),

Fifteenth-century woodcut depicting a medieval banquet where both the king and queen are shown with their tasters. Tasters were nobles who generally came from the royal entourage. Their purpose was to ensure that the food was not poisoned. Before each of the diners is a slice of bread called a trencher. It served as a plate and was changed often during the course of the meal. ROUGHWOOD COLLECTION.

and Holy Cross Day (September 14). Religious were required to fast during the four weeks of Advent, but this was not obligatory for laymen.

Fish was always permitted, for the Church did not promote pure vegetarianism, and the regulations were not made out of compassion for the suffering of animals. It is possible that the fasting cycle was not a Christian invention at all, but an adaptation of medical conceptions about the need for refraining from food during a short period in order to prepare the body for a new season. The physical meaning of the four seasons with their various qualities, derived from the humoral system, was already implicit in the writings of the physician Galen of Pergamon in the second century C.E. The Christian Church adopted this concept and interpreted it by applying it to the avoidance of the capital sins and the devout observance of Lent. The forty days before Easter required a total change-over of the kitchen, especially in those regions that did not have good vegetable oils (like olive oil in Greece, Italy, and Spain) but used butter,

bacon, and lard, as was the case in England, Scandinavia, and large parts of Germany and the Netherlands.

### Food Imitations

During fasting weeks, wealthy people ate a lot of fish, salted like herring or dried unsalted like “stockfish” (i.e., cod that has been split and then unfolded and dried hanging on a stick), but also fresh fish from the sea, the rivers, and the lakes or ponds. Fresh fish was very expensive because of the difficulty of transporting it without ice to keep it cool. Ordinary people who lived far from the water had to be satisfied with salted herring, a popular food of which, however, people tired. Anyone who could afford it tried to stimulate the appetite not only with fresh fish, but also with imitation eggs and meat. Eggs were imitated by mashing white almonds with a mock-yolk that was colored with saffron. Meat could be imitated by forming dough into the shape of an oxshank, like the Dutch *duvekat*, which is seen in seventeenth-century paintings but must have been much older. The marzipan sausages that are still sold in Germany and the Netherlands in December are relics of this medieval custom. Such meat substitutes were common during the Ember days around the Feast of Saint Lucia in December. Other ingredients that were typically used during periods of fasting, especially in Lent, were dried fruits like figs, raisins, dates, and currants, as well as nuts, particularly almonds. Colors were very important in medieval cuisine, not only in these imitation dishes, but in other recipes as well; litmus was used to color sauces flaming red, sandalwood (*Pterocarpus santalinus*) was used for a reddish brown, the juice of parsley and other garden herbs for green, and saffron for a goldish yellow. As mentioned, saffron was originally meant not for the kitchen but for the pharmacist’s shop because of its stimulating influence. Especially in combination with wine, it makes one feel high, an effect that soon turns into a deep fatigue. The Greek pharmacy knew of more remedies that were recommended for their medicinal effects but might at the same time be used as delicacies as well. For example, confitures, prepared with fruit juice and honey, had a laxative effect but were enjoyed by people with normal bowels, too. The best known of these confitures are marmalade or quince jelly (derived from Greek *melon kudo-nion*, which means ‘quince’) and the *diamoron* or mulberry jelly. These recipes from the Greek pharmacy reached medieval Latin medical books, such as the *Antidotarium Nicolai* (Nicholas’s book of antidotes) and the *Regimen sanitatis Salernitanum* (A Salernitan regimen of health) through Syrian and Arabic translations. Greek medical science from the time of Hippocrates (fifth century B.C.E.) and Galen (second century C.E.) had been studied at the School of Salerno since the late eleventh and twelfth centuries.

### Medical Theory

The medical science of the Greeks developed the theory of the four humors or fluids (blood, yellow bile, black

bile, and phlegm), which corresponded with the four human temperaments (sanguine, choleric, melancholic, and phlegmatic). Each fluid belonged to a distinct season and a distinct period of life and had two qualities: blood was humid and warm and belonged to spring and youth; yellow bile was warm and dry like summer and adolescence; black bile was dry and cold like autumn and midlife; and phlegm was cold and humid like winter and old age. In the course of life, a person slowly changed his or her temperament, although some dominant characteristics remained the same. One’s mood also changed a bit with the seasons, in such a way that an adaptation of the body in the Ember days was necessary from a medical viewpoint.

Food played a crucial role in this adaptation because it was held that illness depended not on internal factors but on external ones, mainly on foodstuffs that were contrary to the temperament and age of the patient. The balance between the fluids was disturbed, and the physician had the duty to restore it. An example that still appeals to us is the “hippocras,” a beverage of wine with spices and honey, named after the Greek physician Hippocrates, that was supposed to be warm and dry and for that reason to counterbalance the cold and humid phlegm of a flu. Wine and spices like ginger, cinnamon, cloves, and nutmeg were regarded as “warm” and “dry” and were therefore held in high esteem. Moreover, they were expensive, a fact that may have contributed to their use in high society.

In this way the exotic spices found an expanding market in Europe to such an extent that they altered the dominant taste quite strongly. Alas, cookbooks are lacking for the period between late antiquity and the end of the thirteenth century, so that we cannot tell exactly how and when the use of the many spices became fashionable in monastic and courtly circles. The Crusades and pilgrimages to the Holy Land presumably played a role in this process because more people found their way to the Near East and told about their adventures on their return. Another product of this contact was cane sugar, which was grown in Syria and Egypt and became a major cash crop for the kingdom of Cyprus. It appeared in Western Europe around the twelfth century. Sugar was much more expensive than honey and, like the Asian spices, was only available to the very wealthy.

### Ordinary People

How the mass of the population was fed in these periods is difficult to ascertain because of the lack of documentation. We can suppose that rye bread, grain porridge, lard, sausages, and salted herring belonged to their food supply, together with vegetables like onions, leeks, cabbage, and white parsnips. Certainly some kinds of fruit were consumed, like apples, pears, and prunes, but they were probably processed in pies or stews, not eaten raw. Raw fruits, being humid and cold, were not considered to be healthy.

An illumination from a fifteenth-century French manuscript based on the *Tractatus de Herbis* by the ancient Greek physician Dioskorides. The woman is making fry-bread, round slabs of sweet dough pan-fried in lard or butter. This type of food was eaten only on feast days. © ARCHIVO ICONOGRAFICO, S.A./CORBIS.

### Cookery Books

Our knowledge of medieval kitchen recipes is derived from fourteenth- and fifteenth-century cookery books, of which more are extant than most people think. The most famous cookbook was the *Viandier* of Guillaume Tirel dit Taillevent (c. 1310–1395), who was the chief cook of the French king Charles V. This manuscript was copied several times in the fourteenth century and influenced the other famous French cookbook of the fourteenth century, which is called *Le Ménagier de Paris* (The goodman of Paris) after its anonymous author. The *Viandier* of Taillevent appeared around 1490 in a printed edition that includes not only the fourteenth-century recipes, but also quite a few newer ones that might have originated in the court of the dukes of Burgundy.

The capacity of cookbooks to become bestsellers is also proven by the many printed editions from 1475 onward of the Latin work by the Vatican librarian Bartolomeo Platina, titled *De honesta voluptate et valitudine* (On right pleasure and good health). His book was based on the handwritten cookbook by Maestro Martino, chief cook of the patriarch of Aquileia, who lived in Rome in

the middle of the fifteenth century. Actually, Platina did nothing more than translate Maestro Martino's Italian recipes into Latin and add some medical remarks about their qualities as related to the humoral theory. Maestro Martino's recipes, although more often than not qualified by Platina as unhealthy, can be easily imitated and enjoyed today. They were derived partly from Byzantine as well as Spanish-Catalan cuisine, of which a fourteenth-century cookbook, *El libre de Sent Sovi* (The book of Sent Sovi), is known. There the Armenian Arabic influence is notable, for example in the use of mashed almonds stirred with cooking liquid for the binding of sauces and stews, and of pasta in strands like spaghetti. The use of ground almonds became common practice in high cuisine all over Europe, but pasta in strands remained limited to the Mediterranean regions: in Italy several varieties were developed, like vermicelli and macaroni, along with pasta in sheets like lasagna, which was probably known already by the Romans.

No less professional a cook than Maestro Martino was Maistre Chiquart, who wrote his book *Du fait de cuisine* (On cookery) while in the service of the Duke of

Savoy around 1420. A little bit earlier, around 1390, a collection of recipes from the English royal household was composed under the title *The Forme of Curye* (The way of cookery). Several other English collections of recipes date from the fifteenth century. In the German language the oldest known collection of recipes is *Daz Buoch von guoter spise* (The book of goodly fare), which was composed in Würzburg around 1350 by a high official of the bishop and, therefore, probably reflected the food served in an ecclesiastical household. But there are also some recipe collections from secular German courts, for example, the cookbook of Maister Eberhard, cook of the duke of Bavaria-Landshut in the fifteenth century. All of these handwritten texts are now available in modern editions. The earliest printed German cookbook is the *Küchenmeisterei* (Mastery of the kitchen), which was published in Nürnberg by Peter Wagner around 1490.

As for the Netherlands, the series starts rather late with some fifteenth-century written recipe collections and a cookbook printed in Brussels around 1514 by Thomas van der Noot, called *Een notabel boecxken van cokeryen* (A notable book of cookery). Why this occurred so late is difficult to tell: Is it because older texts are lost or because Dutch courts mainly used foreign cookbooks? Certainly the bourgeois cuisine of the Low Countries, for which the *Notabel boecxken* was intended, was deeply influenced by French and German as well as English sources.

In general, we should realize that handwritten and printed cookbooks in the Middle Ages were only accessible to educated people, who were able to either read themselves or have the books read to them: ecclesiastics, noble ladies, and wealthy bourgeois. The foodways of the average population in towns and villages can therefore not be learned from cookbooks.

With the invention of printing and the advance of teaching in town and chapter schools, the number of people who could read and write increased, as did the readership for cookbooks. Could a book like Platina's *De honesta voluptate* even be counted among the bestsellers? We must ask, however, whether these books were meant for use in the kitchen or rather as showpieces in the owner's library. A Latin collection of recipes with medical remarks like Platina's is more conceivable in the latter case. Innovations in culinary practice are not to be found there but rather in sixteenth-century handwritten household collections that were sometimes later printed.

## The Renaissance

A remarkable innovation of the Renaissance was the return to the natural taste and shape of the ingredients, which came about under Italian influence in reaction to the medieval predilection for faux preparations and spiced stews. Certainly, the sausages made of marzipan did not disappear—on the contrary, as cane sugar became cheaper, people could indulge in the luxury of more imitated animals and other sweets—but such items were dri-

ven to the edge of the dinner instead of being the main course. Fish was now allowed to taste like fish with a simple sauce of boiling liquid and vinegar. A novelty was the consumption of raw salads with a dressing of oil, vinegar, pepper, and salt. Salad comes from *insalata*—‘salted’. In Italy the habit of eating green leaves with *garum* or salt had never been dropped, and although it was contrary to the medical theory about the humid and cold qualities of raw vegetables, this practice slowly reached the regions north of the Alps as well. By way of concession, however, the physicians advised placing the salads at the beginning of the meal, in order that the warm and dry dishes that would follow them could correct their injurious qualities.

Under the influence of the Protestant Reformation, the fasting prescriptions of the Roman Catholic Church were gradually mitigated, so that the strict prohibition of animal fats like butter and lard during Lent was dropped. It was in precisely those countries that did not possess good vegetable oils and had therefore always experienced the greatest impediments during periods of fasting, that the Reformation gained its staunchest adherents—perhaps not by accident. So dairy products became more important in the kitchen, and in the coastal regions along the North Sea a remarkable increase in the number of dairy cattle can be observed in the sixteenth and the beginning of the seventeenth centuries, in comparison with former ages, when horned cattle had been raised mainly for their meat. A larger output of butter and cheese was the result, together with more recipes for sour and curdled milk.

Through the discovery of America, many new plants became known that were more or less successfully introduced in Europe. Travels to India over the sea made the Asian spices available to many more people: they became cheaper and ceased to be a status symbol. This fact certainly played a role in the change of tastes back to the natural flavors of foods and away from the camouflage of sharp sauces and stews.

In this way, the mainstream of history always has exercised its influence upon our civilization and upon our eating habits as well. Next to long waves and secular trends in our foodways, those habits always have been moving and changing.

**MIDDLE EAST.** The Middle East is that part of Western Asia extending from the eastern Mediterranean coast of Turkey and Syria, through the desert to Iraq and Arabia, and to the East through Iran to the Caspian, the Caucasus, and the Black Sea. Into Africa, it includes Egypt, and, by some accounts, Arab North Africa. This

area comprises mountains, deserts, fertile plains irrigated by grand rivers, and seacoasts. Climatically, the Middle East ranges from the temperate Mediterranean coast, to the extreme heat of the arid desert areas, to snowy mountains. This variety of terrain produces a wide range of food ingredients.

### The Population

The ecology of these lands fosters different modes of adaptation. Nomadism was a prevalent form of existence for much of the history of the region, and remains so on the margins. Equally, the region saw the earliest agricultural settlements and the first cities in human history. Indeed, the contrast and conflict between nomad and city dweller is an ever-present theme in the culture, lore, and politics of the region from earliest times. Ethnically, it embraces Arabs, Persians, Turks, Kurds, Armenians, and, until recently, Greeks, as well as many pockets of ancient ethnicities and religions. Jewish communities, many of ancient ancestry in the region, partook in this ethnic diversity, most of them now settled in the state of Israel, which also includes many European and African Jews, creating a melting pot of diverse cultures and cuisines.

Islam is the majority religion in the Middle East and enters into the constitution of many of its cultural elements, including food and drink. There are many Christian communities, of diverse denominations, and their religious prescriptions of feasting and fasting have also left their mark on food culture. Ancient religions and sects persist in some quarters, notably the Zoroastrians of Iran, as well as many sects, such as Baha'i, professing syncretistic combinations of old Persian religion with Islam and Christianity.

### History and Culture

Successive conquests and rule of different empires have shaped the civilizations and cultures of the region, and led to the common themes in its culture that we find today. The ancient civilizations of Mesopotamia and Egypt were subject to subsequent conquests and incorporation in wider empires, starting with the Persians and the Greeks, then the Romans, including Byzantines, which Hellenized much of the region. The Muslim Arab conquests established a vast political entity, soon fragmented, but retaining common cultural elements. The Islamization of much of Iran and the Byzantine Empire brought these elements of older cultures to shape the emergent civilization, notably its culinary elements. The last empire to rule the region (before European colonial rule) was the Ottoman, which also included much of southeast Europe, creating a wide cultural synthesis of Turkish statecraft, Arab religion, Persian culture, and many elements from the territories under its control. This synthesis included the food cultures. An important epoch in the history of the region, which also affected food culture, was that of Arab Spain, from the eighth to the fifteenth centuries. Moorish Spain created its own cultural

synthesis, which is evident in Spain and North Africa to the present day. Spain and Morocco never came under Ottoman rule, and this exclusion, as well as distance from Ottoman lands, has left its traces in the distinction of Moroccan food culture.

### Ingredients, Techniques, and Cooking Media

**Cereals and breads.** Cereals constitute the bases of the Middle Eastern diet, historically and today. Wheat and rice are the major and preferred sources of staple foods. Barley is common in the region and is an ingredient in cheaper bread, and millet and sorghum are used in a few places to make porridge and gruel. Maize became common in some areas, notably the Black Sea coast of Turkey, as well as in parts of Egypt. It is made into a kind of cake and eaten as bread. A wide range of breads are baked, mostly from wheat, but also in combination with barley. Bread is generally leavened. Flat breads are the most common. Naan in Iran, *pide* in Turkey, *khubz* or *'aysh* (more of a generic term for bread) are all similar forms of flat bread made from leavened and risen dough in an oven. In Iran and many Arab lands as well as in Anatolia, a *tannour* or *tandir* is the most common oven: an earthenware pot built into a wall or freestanding, is fired with wood or charcoal, and disks of dough are stuck to its sides until baked, usually soft with crisp edges and a bubbly surface. Modern, industrial ovens are becoming more common for large-scale commercial production, which include both flat breads and European

style loaves. Another kind of flat bread, called *lavash* in Iran and Turkey, or *khubz saj* in Arabic (also *saj ekmegi* in Turkish), is cooked over a concave iron pot, a *saj*, much like Indian chapati. Bread is a universal staple in the region, eaten, in one form or another, by all classes and groups, practically at every meal.

Another common use of wheat is in the forms of bulgur (Turkish; in Arabic, *burghul*) and couscous. *Burghul* is cracked wheat, made by partially cooking the wheat grains in water, drying it in an oven or in the sun, then breaking it into pieces, in different grades of size. It is used as a staple in a wide area covering Anatolia, Syria, and northern Iraq. Typically, it is cooked in water, with flavorings, much like rice. It is also used in making meat pies, *kibbel/kubba* (see below), and as an ingredient in salads, notably in tabbouleh, with chopped parsley, tomato, lemon, and oil. Couscous, almost exclusive to North Africa, where it is a staple, is made from rolling semolina grains (mostly durum wheat, but it can be barley) in flour, to make a kind of cross between grain and pasta. This is typically steamed and served as a base to meat and vegetable sauces. Another wheat product is *frik* or *frik*, cracked green wheat, sometimes from burned fields, to give a smoky flavor. It is used much like *burghul*, but considered finer.

### Rice

Rice is produced in particular parts of the region with suitable climate, soil, and water. Notable rice-producing

areas include the Caspian provinces of Iran, the delta of Egypt, and the marsh area of southern Iraq (before its recent drainage). In the areas where it is produced, rice can be a staple, to the extent of making bread from its flour in southern Iraq. Elsewhere in the region, rice was considered a luxury item to be eaten on special and festive occasions. *Burghul*/bulgur in wheat-producing areas was considered a cheaper substitute for rice, such as the *bulgur pilavi* of Anatolia (*pilav* originally referred to rice).

There are many types of rice produced and consumed in the region. Varieties that cook into separate grains (*ruz mufalfel*) are the most valued, and aromatic varieties are also prized. Traditional varieties in Egypt and Turkey were mostly round or boat-shaped grains, much like Italian rice, while in Iran and Iraq, mostly slender, long grains were grown. In recent years, however, much of the rice consumed in the region is imported from North America or the Far East. Basmati rice from India-Pakistan is highly valued: it is aromatic and produces the desired separate grains. Cheaper long-grain varieties are common.

There are a number of different cooking procedures for rice. Iran boasts the most elaborate and refined rice cookery. The standard procedure there is for the rice to be washed in several changes of water, ostensibly to remove the starch (it is not clear that this operation is necessary with modern rice varieties), then it is soaked in water for at least one hour, but preferably for much longer. It is then drained and thrown into boiling salted water for a few minutes, until grains are just cooked, at which point it is drained (much like cooking pasta), then returned to the pot over some fat, oil, or melted butter; the pot then is covered with a cloth and a lid, and left over a low flame for at least half an hour. Known in Iran as *chelow*, this plain rice is served under grilled meats (*chelow kebab*) or with meat/vegetable stews (*khoresht*). More complex rice dishes are called *polow* (*pilaf*, used in Turkish for all rice dishes). When the rice is drained after boiling, it is then layered in the pot with meats and/or vegetables and/or sauces, as well as nuts, currants, or other dried fruit in some dishes, and always with some fat or oil, then covered and steamed as with *chelow*. These methods of cooking are also followed in some communities in Iraq and in Anatolia. More typical methods of cooking in Turkey and the Arab world involve covering the raw rice (sometimes after washing and soaking) with just enough water to cook it, adding salt, and perhaps aromatics, as well as oil, then boiling until the water is absorbed, at which point it is covered and allowed to steam. More complex rice dishes are prepared by first frying the raw rice in oil or butter, sometimes with onions or other aromatics, then adding water or stock, sometimes with meat or vegetables, and allowing it to cook in the same way.

### Oils and Fats

Butter and clarified butter (called ghee in India) are, traditionally, the preferred medium of cooking for those

who can afford them. Olive oil is prevalent in the Mediterranean coastal areas. It has many nonculinary uses, such as in making soap and as a lighting oil (which is how it is mentioned in the Qur'an). It was used for cooking predominantly by Christians and Jews. Christians use it during Lent, when meat and dairy products are excluded, and Jews use it in place of animal fats such as butter to avoid mixing meat and dairy products. In regions where olive oil was not prevalent, as in Iraq, Iran, and most of Egypt, Christians and Jews used other oils, mainly sesame.

In Turkish cookery a whole class of vegetable dishes is labeled *zeytinyagli*, a reference to olive oil. These are usually eaten cold. In the refined cookery of the urban upper classes, butter was used for cooking meat, poultry and rice, while oil would be used for cooking or dressing vegetables or salads.

Another cooking medium is rendered meat fat, especially that derived from the fat tail of a local breed of sheep. Traditionally much appreciated and featured in historical recipe books and manuals of the princes and the upper strata, it is now largely avoided on account of its strong odor and the health worries of consumers. In recent times, modern industrially produced vegetable oils predominate in the region, and seem to have replaced butter and olive oil in cooking. Cheapness and convenience, as well as perceived health benefits, are involved. The use of olive oil persists in particular regions, such as coastal Tunisia and parts of Aegean Turkey, where there are strong traditions of its consumption, although even there, cost diminishes its accessibility to the poorer sectors.

### Spices and Herbs

Most regions in the Middle East use spices. Typically, a stew will include a small amount of a spice mixture called *baharat*, which includes cinnamon, clove, cumin, and coriander. Black pepper is common, and chili peppers are used occasionally, especially as a separate sauce, or as a pickle. Some dishes require specific spices, such as *kamouniya*, a meat stew with cumin, or the Egyptian *molokhiya* (see below), with coriander. Iranian cookery features a more extensive use of spices, including the pungent fenugreek leaves and whole dried limes.

Parsley is commonly used in cooking and in salads, and so is mint. Varieties of thyme are common in Syria, Lebanon, and Palestine, and a mixture of dried thyme and sumac, crushed sour berries, is a common breakfast item with oil and bread. Sumac is also sprinkled over grilled meat. Garlic is common to many dishes and salads.

### Meat, Poultry, and Fish

Lamb and mutton have always been the favored meats of the region, with veal as a subsidiary choice in some instances, and, in other places, goat. Pork, prohibited in the religions of Islam—though there are accounts of wild boar being hunted and eaten by some Bedouins—and

Judaism, was also largely avoided by the Christians of the region. Beef was generally considered to be an inferior meat, consumed, if at all, by the poorer classes. This may reflect the quality of the beef it was possible to produce on the sparse pastures of the region. Beef, however, was considered suitable for certain dishes, such as *harissa*, a porridge of pounded grain and meat. Camel meat was consumed in some parts, but is not so commonly now.

Prominent among the meat preparations were the grilled meats, kebabs, which distinguish the region. There is a wide variety of these grills, with many regional specialties and styles. The most common are the cubed cuts on skewers, known as shish kebab in most places, but *tikka* in Iraq (and India). Chicken may also be grilled in the same fashion. Another common variety is *kofita kebab* (*kebab kobedeh* in Iran, or just *kebab* in Iraq), made from ground meat, sometimes with onions and spices, shaped around the skewer like a long sausage and grilled. A popular kebab of recent origin is the *doner kebab*, also known as *shawarma* in much of the Arab world (*gass* in Iraq). It is either layers of meat and fat or a shaped ground meat loaf, placed on a large skewer that rotates vertically next to a strong heat source that cooks the outside crisp. The cooked outside pieces are then sliced off and served with bread and salad. There are many other types of kebab: ribs, thin slices of meat wrapped around a skewer; small cubes of liver, kidney, and sweetbreads, sometimes alternating on a skewer with cubes of fat (*kofte* or liver); wrapped in caul fat, like a sausage, and many others.

Kebab is typically a street or restaurant food, served with bread (rice in Iran), salad, and pickles. It is not usually prepared in domestic kitchens. In recent years, kebab, and especially the *doner/shawarma* variety, have become regular features of fast-food joints in European and American cities.

Meat and vegetable stews, served with rice, bulgur, or bread, are the other genre of typical meat preparation in the region. A typical domestic meal for those who can afford meat would be a stew of lamb in butter or oil, with onion, tomato (usually as paste), and spices with one vegetable, such as okra, beans, or aubergine (eggplant). Often poorer families would use little meat, usually on a large bone, to flavor the stew. There are many variations on this theme, including the distinguished Iranian stew of *korma sabzi*, of lamb in butter and a mixture of green herbs minced fine, as well as whole dried limes, often with the addition of red kidney beans or split peas.

Offal, tripe, heads, and feet are much appreciated in many quarters. A typical broth found in practically all parts of the region is *kelle pacha*, made with sheep heads and feet. This is typically found at a street or specialized restaurant, which is often open all night or very early in the morning, catering to early-rising workers for breakfast, and to revelers after a night of partying and drinking.

*Kibbe* (Syria) or *kubba* (Iraq) is a genre of pie or dumpling made with meat and cereal. The most common

are made with ground meat (typically lamb) and *burghul*, worked together like a dough, then stuffed with minced meat that has been fried with onion, aromatics, and, sometimes, pine nuts or almonds and raisins. This can either be in the form of individual small dumplings (usually shaped like a torpedo), or in slices like a cake, baked on an oven tray with the stuffing placed between two layers of the dough. In the form of small dumplings, this can also be cooked in a sauce with vegetables. One striking variation is a *kibbe niyye*, raw *kibbe*, made by pounding lean meat and *burghul* together with seasoning, which is then served as small dumplings, sometimes with dips of lemon juice and chili sauce. In Anatolia this genre is known as *kofte*, in common with other ground meat *rissoles*: the stuffed version is called *icli kofte*, and the raw one is *cig kofte*. In Iraq and Iran, there are versions of this dumpling made with rice instead of *burghul*.

**Poultry.** Chicken is ubiquitous in the region. Squab pigeon is eaten in some parts, notably Egypt and Morocco. Wild fowl, especially duck, quail, and pheasant, are appreciated by some, especially in the Caspian region of Iran, but also in many other parts where there is a tradition of hunting.

In the past, before the introduction of industrial production of chicken, these birds were tough, and were generally boiled and stewed, often in sauces and vegetables, just like meat. If they were to be fried, they would be boiled first (in pieces), then finished in a frying pan in oil or butter. A banquet dish would be chicken stuffed with rice or some other grain with meats, nuts, and aromatics, then stewed or baked in butter and further aromatics. Modern battery hens are tender and do not require boiling or long cooking. But old habits persist, especially in domestic kitchens, though many cooks are now roasting and frying their chickens.

In Egypt, pigeon is served grilled (after being spatchcocked, or opened flat) or stuffed, typically with rice or *firik*, and baked or stewed.

Wild fowl are cooked in a similar fashion as chicken. One unique dish of wild duck comes from Caspian Iran and is called *faisanjoun*. The pieces of duck are stewed in a sauce of pomegranate syrup and walnuts. This dish has now become popular all over Iran and in parts of Iraq, but chicken is substituted for the duck. Iranians regard it as one of their foremost national dishes.

Fish cookery and consumption tend to follow specific local tastes and styles, depending on local varieties, forms of fishery, and, sometimes, religious beliefs. Even the names given to the same fish vary widely, and in Mediterranean regions, often follow Greek or Italian derivations. Fried or grilled fish are the most common, as indeed elsewhere in the world. However, local styles are important even for simple grilling. In Baghdad, for instance, Tigris fisherman developed a method of grilling the local carp and barble (called *shabbout*, and highly valued, now almost extinct), by opening the fish flat, like a

kipper, and skewering it on robust sticks, which are then erected around an open wood fire on the ground. This is called *masgouf*, and Iraqis came to consider it as a national dish.

Istanbul and the Aegean region of Turkey have a rich and varied fish culture, as does the Black Sea region. There are numerous fish restaurants and bars (known as *meyhane*) along the shores of the Bosphorous, serving varieties from the Mediterranean and the Black Sea. A notable fish from the latter is *kalkan*, a kind of turbot that is much appreciated. They also feature sea bass, different types of bream, a kind of bonito, and mackerel. These are fried or grilled, or sealed in paper, foil, or a salt crust and baked. A typical Turkish dish is *buglama*, a kind of fish broth. Any of these fish or *hamsi*, the small anchovy-like fish from the Black Sea, are boiled in a broth of vegetables and aromatics, with oil or butter, and served in the pot. Fish stews are common elsewhere, such as the *salona* of Iraq, in which fillets are stewed in onions, tomato, tamarind, and other spices.

In many regions, fish is cooked or served with rice. In Iran, fried fillet of fish is served over *sabzi polow*, “green” rice, cooked with a herb mixture. *Sayyadiya*, “fisherman’s dish,” is typical of the Syrian coast, in which pieces of fish are fried with onions and spices, then cooked with rice. In the Black Sea region of Turkey they have *hamsi pilavi*, combining rice with the fried small fish. Similar dishes are found all over the region.

Seafood, in the sense of crustaceans and mollusks, such as shrimp, crab, squid, and mussels, are available in the coastal region, but not always consumed. There is a widespread religious taboo against this genre, similar to the Jewish prohibitions. It is not, however, common to all Muslims, but confined to particular interpretations of religious law. These foods are widely appreciated in Istanbul, the Aegean, Alexandria, and parts of Syria and Iraq. A typical street and bar food in Istanbul is mussels stuffed with rice, pine nuts, and raisins.

### Vegetables and Pulses

Vegetables and pulses are the predominant everyday food of the great majority of the people of the Middle East. They are boiled, stewed, grilled, stuffed, and cooked with meat and with rice. Among the green leaf vegetables, many varieties of cabbage, spinach, and chard are widely used. Root and bulb vegetables, such as onion and garlic, as well as carrot, turnip, and beet are equally common. Fruit vegetables include marrow or squash, tomato, and eggplant. *Bamia* (okra or gumbo) is a distinctive element in the cookery of the region, appreciated for the peculiar consistency of the stews made in combination with meat, tomato, and spices, often with a sour flavoring. A similar consistency is achieved with *molokhiya* (mallow), a green leaf, used fresh or dried, chopped up fine and cooked in a broth with chicken or meat. This is most common in Egypt, where, traditionally, it was cooked with rabbit. Aubergine or eggplant is perhaps the most

distinctive vegetable of the region, cooked and served in diverse fashions. It is fried in slices and dressed in yogurt and garlic; or roasted over an open fire, then pulped and dressed with tahini (sesame paste), lemon juice, garlic, and cumin, a dish known as *mutabbal* or *baba ghanmush*; stuffed with various ingredients and roasted in the oven, as in the famous Turkish dish of *imam bayeldi* (“the imam fainted!”); pulped into a sauce for meat in the Turkish *hunkar begendi* (“the king liked it”); or combined with meat in various stews. Tomato, a relatively recent import from the New World (it arrived in most places in the nineteenth century), is now the most ubiquitous ingredient in Middle Eastern cookery. It is used fresh in a variety of salads, cooked, either from fresh tomatoes or as a preserved paste, in almost every stew and broth, and grilled with kebab.

Beans and pulses are crucial to the diet of the region, second only to cereals. The fava bean (broad bean in England) is original, indeed ancient, to the region. Known as *foul* in Egypt and Syria, and *baqilla*/*baqelli*/*bakla*, in Iraq, Iran, and Turkey, they are eaten green and dried. Dried, they are boiled in one of the most popular Egyptian foods of *foul medames*, a domestic and street food, eaten for breakfast or any other meal, mashed and dressed in oil, lemon, and chili. Similar dishes are found in all other parts of the region. The famous *ta’miyya* or falafel, now popular in Europe and America, was originally made from dried fava, crushed and formed into a *rissole* with herbs and spices, then fried. It is also made from chickpeas, or a mixture of the two. Green fava are cooked like other green beans, boiled and dressed in oil, or stewed with meat. A famous Iranian dish is *baghelli polow*, green fava with rice and dill, often with meat; versions of this combination are found elsewhere. The haricot bean (*fasoulyia*) is used fresh or dried, boiled and dressed, sometimes as an accompaniment to grilled meats, or stewed with meat. Black-eyed beans (various names, mostly *loubia*) are typically used dried, boiled, often with green leaves, and dressed in oil and lemon.

Lentils, split peas, and chickpeas are widely used in soups, with rice, in salads, or with meat. *Homous bi-tabina*, made from chickpeas and sesame paste, is now common throughout the world, but originated in Syria/Lebanon. Lentils are cooked with rice in various dishes, notably *mujadarra*, found in many parts of the Arab world, as well as in adaptations of the Indian *kichri*. This latter, in the form of *kushari*, is the most popular street food in Egypt. Macaroni is added to the rice and lentils to extend its bulk with a cheaper ingredient, and the taste is enhanced with fried onions and a chili sauce.

Stuffed vegetables are a dish most associated with the Middle East in the popular mind. They are commonly called *dolma*, the Turkish word meaning “stuffed,” but also the Arabic *mahshi*. *Yaprak*, “leaves” in Turkish, often vine leaves, but also chard and cabbage, are stuffed with rice, ground meat, pine nuts, and spices, then stewed in oil and tomato, and, less commonly, with a small

amount of rich meat such as sheep's feet or breast. There is a version without meat, cooked in oil and served cold, known as *yalinci dolma*, or "false dolma." Many vegetables are similarly stuffed and stewed or baked, such as squash, onion, tomato, eggplant, peppers, and even carrots. There are many regional and local variations of ingredients and flavorings, such as the use or not of tomato or lemon, or the addition of sugar.

### Dairy Products

Milk, fresh or soured, was commonly consumed by Arabs, with camel milk predominating in Bedouin regions. Yogurt, a Turkish contribution, is commonly consumed plain, used in cooking, used in salad dressing, or diluted as a drink (Turkish, *aryan*). Butter, as we have seen, was the favored cooking medium. White cheese, like the Greek feta, is the most common in the region, the best made from sheep or goat milk, as is the much valued *balim* or *baloumi*. There are many local and little known cheeses, especially in the mountainous regions of Anatolia, Kurdistan, and Lebanon, which offer rich pastures.

### Meals

Patterns of consumption depend, of course, on class, region, and communal affiliation. Desert nomads, for instance, consumed milk, fresh or soured, butter, if affordable, and dates with bread at most meals. Meat was a luxury eaten on festive occasions when a camel or a sheep was slaughtered, boiled in great cauldrons, and served on rice with copious quantities of butter, a rare delight. Rural inhabitants had similarly limited diets. Egyptian peasants, as well as the urban poor, eat a great quantity of bread (often at subsidized prices) combined with a little salted cheese and onion. Anatolian and Syrian peasants eat much cooked *burghul*/bulgur, sometimes with yogurt, in season with tomato. Many urban workers purchase many meals in the street from vendors of *kushari* (rice, lentils, and macaroni) in Egypt, *foul/daqella*, in that country and Iraq, boiled turnips and beets, roasted corn, kebab, and bread with everything, in many parts of the region depending on income and season.

Historically, meal patterns varied greatly, and the one feature that seems to be common to all regions and classes was a large midday meal. Most people also ate something in the evening, usually a lighter meal. Now the daily three-meal pattern is common among the urban classes, especially the more prosperous.

Breakfast, if eaten, was not usually a distinctive set of foods, but items and leftovers from other meals. Balls of boiled rice washed down with tea in Caspian Iran, for instance, or the ubiquitous foul or *kushari* in Egypt. Prosperous households would serve grilled meats or stews for breakfast. Over the course of the twentieth century, many of the urban prosperous and middle classes have come to regard breakfast as a specific meal, influenced by Western models. Breads or pancakes of various kinds with butter, yogurt, and preserves are often served, as well as eggs in various forms.

Lunch and supper are not distinct from one another. Which one is more substantial depends on work patterns and lifestyle, mostly now tending to the Western pattern of emphasis on an evening meal after work, at least for the upper and middle classes. Except, that is, on weekends, holidays, and festivals, when larger lunches are eaten. A typical Middle Eastern meal would consist of a stew of meat (or chicken) with a vegetable, such as beans or *bamia*, served with rice and bread, and perhaps a salad. Soup, fried fish, roast chicken, or grilled meat are possible additions or variations. The meal finishes with fruit, and sometimes other sweets or pastries. Historically, however, pastries and sweets were not eaten at the end of the meal, but as a separate snack or as a meal in itself. To this day, poorer people lunch on pastries as a special treat.

### Eating Out

Restaurants are not traditional to the region, but have developed over the course of the twentieth century. Vendors of cooked food, however, are traditional, and continue to do good business in Middle Eastern cities. The central market areas of cities are redolent with the smells of grilling meat and onion from the kebab stalls, of *kibbe* or falafel frying, displays of pastries, sweet and savory. Tales of the *Thousand and One Nights* feature many of these cook shops and their wares. You see people standing, sitting on stools, or crouching around these stalls, sampling their wares. Historically, many urban people did not have domestic kitchens and sent out for their cooked food, as did market people in their shops and workshops, and many still do. The vendors also cater to the customers of surrounding teahouses, taking food to their tables where they are drinking tea, smoking, and playing games. Now, of course, pizza and hamburgers are added to the repertoire of street food.

### The Tavern and the Meze

A type of food specifically related to drink is the meze. Drinking alcohol and drink cultures are widespread, especially in the Mediterranean regions. Historically, wine was the most common alcoholic drink, but during the twentieth century, distilled liquor (typically *arak* or *raki*) became common, and more recently beer. Historically, most "respectable" people who drank did so at home, with friends. Taverns were rough and low-class. The making, distribution and serving of alcohol were carried out predominantly by Christians—in Turkey mostly by Greeks and Armenians—and they were usually the tavern keepers. This picture changed over the course of the twentieth century. An increasingly cosmopolitan, modern, and educated middle class patronized public places of entertainment and association, including cafes, bars, and restaurants that served alcohol. That is where the distinctive meze developed into a kind of convivial meal around the drink table. It consists of a number of small dishes (*mezze* is a Persian word meaning "taste"), picked at leisure: cheese, melon, nuts, various salads and dips, such as *tabboule* (chopped parsley, tomato, and a few grains of

A chef prepares falafel in a restaurant kitchen in Cairo, Egypt. © HANS GEORG ROTH/CORBIS.

*burghul*), *homous* and *mutabbal*, pickles, and also more substantial items, such as grilled meat, *kibbe*, and sausage. The centers of excellence of meze preparations were initially the Middle Eastern cities with a strong Christian presence, such as Istanbul, Beirut, and Aleppo, but it later became more general, and meze is now widespread in Europe and America, primarily through Lebanese restaurants.

### Feasting and Fasting

Festivals and fasts, mostly religious, are celebrated with particular foods, which vary by community and region.

Ramadan, the fasting month for Muslims, is the most important occasion in this respect. Paradoxically, it is the month during which food consumption increases dramatically throughout Muslim communities. Fasting is prescribed for the daylight hours, to be broken at sunset of each day, then people can eat and drink through the night, until daybreak. Breaking the fast becomes a banquet, with exchanges of invitation between kin and friends, and public banquets held by charities and associations. The cafes and pastry shops are open at night, and a carnival atmosphere prevails in the streets. Many Muslims, following the reported example of the Prophet,

break their fast with a date, followed by a variety of dishes. A common Ramadan dish in many regions is *harisa* (Arabic), *kesbke* (Turkish), or *balim* (Persian), a porridge of meat (often beef) and wheat, boiled then pounded to a paste, spiced with cinnamon and sometimes sugar, or fried onions and strong spices. Lentil and other substantial soups of meat broth and pulses are common items. Otherwise, the Ramadan table consists of a selection of the popular local foods, of rice dishes, fava beans, salads, and dips, and so on. Sweet pastries and puddings are ubiquitous on Ramadan nights everywhere, and the large-scale consumption of dates is common. A common drink for breaking the fast is that made from *qamareddin*, dried apricots pulped and dried in sheets, like paper, which is found throughout the Arab world.

The end of Ramadan is marked by a festival, *Id 'al-Fitr*, a feast that breaks the fast, during which a great quantity and variety of sweets and pastries are consumed. The other major Muslim feast is that of *'Id al-Adha*, feast of the sacrifice, which occurs during the pilgrimage month, and at which an animal, usually a sheep or a goat, is slaughtered in every household that can afford it, and great banquets are prepared, with an obligation to give food to the poor.

Lent, the Christian fasting period before Easter, is distinguished by its own foods, dishes that avoid meat and dairy products. This generates a great many dishes made with vegetables, pulses, and oil, many of them described above.

**Jewish Saturday meals.** Every Jewish community has its typical Saturday dish, one that is prepared on Friday (Cholent) and cooks overnight for Saturday, preferably with the means to keep it hot, but with an extinguished fire. Iraqi Jews, for instance, prepared a dish of stuffed chicken with rice called *tebit*, “overnight.” The chicken is stuffed with rice and aromatics, boiled in a broth with tomato paste and spices, then more rice is added to the broth; the whole ensemble, in a large pot, is then put over a wood fire, covered with old blankets and cushions (to keep the heat), and allowed to cook slowly overnight. At Saturday lunch, the fire will have been extinguished, allowing the handling of the food without fear of breaking the Saturday rules. Eggs were placed over the rim of the pot to cook slowly, and these were eaten for breakfast.

Ancient festivals, pre-Islamic and unrelated to the existing religions, are also celebrated with food. *Nowrouz* is the Persian New Year and spring festival, falling at the spring equinox in March. It is celebrated in Iran, Kurdistan, and some parts of Anatolia and Iraq. The *haft-I sin* (seven S’s) is a tray on which seven symbolic items, all of whose names begin with the letter “S,” are displayed in every household: these include apple, garlic, and vinegar. Part of the ritual of this feast is eating in the open air, which engenders many picnics in parks, gardens, and in the countryside. Another spring festival is the Egyptian Shamm al-Nasim, “the breathing of the breeze,” which also requires eating outdoors and having picnics. *Fasikh*, the traditional dish for this festival, is best eaten outdoors, as it consists of rotted fish (usually mullet) eaten with raw onions.

## Globalization

Global commerce, travel, tourism, and the new media have affected Middle Eastern food patterns in diverse ways. Most commentators note the spread of Western fast foods, such as hamburgers, pizzas, and fried chicken—in what has been dubbed “McDonaldization.” But this is only one part of the story. Another is the region’s development of standard restaurant repertoires, based largely on Lebanese styles, and the spread of these styles to Europe and America: McDonald’s in Cairo and *shawarma* in New York. Another element has been the “invention of tradition”: placed on the global stage through tourism and communications, caterers and cooks responding creatively to the demand for “authentic” national and local cuisines. Many hotels and restaurants in Istanbul are reviving a so-called Ottoman cuisine, and grand hotels in Cairo are serving *foul* and *ta’miya*, as well as obscure village dishes, to tourists. Globalization, then, does not necessarily lead to uniformity in cuisine, but to diversity, and hopefully, to creativity.

**MILITARY RATIONS.** Rations are the foods issued to soldiers, particularly those given when they are engaged in field operations. Since rations are often carried over long distances, they have to be as nonperishable as possible. Dry bread and salted meat were the mainstay of soldier’s fare until modern preservation techniques were developed.

In the days of the Roman Empire, soldiers on active service were supposed to get two pounds of bread per day, plus meat, olive oil, and wine. If baker’s bread was not available, the soldiers were given grain that could be mixed with water to produce a gruel or porridge, or baked into flat (unleavened) bread. In the Byzantine army, the soldiers were given *paximadion*, a biscuit baked twice to make it light and, more importantly, very dry, since it would keep better that way than bread with any moisture in it.

From the fall of Rome to early modern time, armies in Europe were typically small and temporary. They col-

## NAVAL RATIONS

Soldiers' food in times past was bad enough. Sailors on long voyages had it even worse, subsisting mainly on ship's biscuit (similar to soldiers' hard bread) and salted beef or pork. The meat often stayed in casks for years before being opened, and was distinctly unappetizing: "It was of a stony hardness, fibrous, shrunk, dark, gristly, and glistening with salt crystals," as the British poet and historian John Massfield put it. A sailor handy with a knife could turn a chunk of salt beef into a box or other useful item. The lack of vegetables and fresh food led to scurvy, a disease caused by vitamin C deficiency that could decimate crews on long voyages. The British eventually solved the scurvy problem by issuing sailors lemon or lime juice. The juice ration gave rise to the nickname "limeys" for British seamen.

lected grain for bread and animals for meat; when on the march, they depended largely on supplies purchased or simply taken from civilian populations. Before setting off on an expedition to France in 1294, for example, Edward I of England procured cattle and swine to be slaughtered for meat, and salt to preserve it. Bread, flour, and wheat were also issued to the units for the soldiers to eat. Records indicate that while some of these supplies were purchased on the open market, others were requisitioned from apparently unwilling sellers. Forces heading off on longer trips, such as Crusaders, carried hard money to buy provisions along the way.

When more permanent armies were established, the problem of sustaining them on the march was again solved with bread and salted beef or pork, plus dried peas or beans. The Continental Congress decreed in 1775 that the daily ration for soldiers was to consist of a pound of beef, three quarters of a pound of pork, or a pound of salted fish, plus a pound of bread or flour, along with a pint of milk and a quart of spruce beer or cider to wash it down. Quantities of peas, beans, and rice or cornmeal were also allotted. Unfortunately, these generous rations were often not available, the Continental supply system not being up to the task.

In the American Civil War (1861–1865), soldiers on both sides ate salted beef or pork and made johnnycakes out of flour and fried them in bacon grease, or kneaded the dough into a long roll, wrapped it around a ramrod, and roasted it over a fire. They became accustomed to hard bread, or hardtack, so hard that the best thing to do with it was to smash it with a musket butt and soak it in the soup or coffee. The federal army attempted to provide a more balanced meal through a concoction of dehydrated potatoes, cabbage, turnips, carrots, parsnips, beets, tomatoes, onions, peas, beans, lentils, and celery called "desiccated vegetables." The soldiers had little luck trying to cook the newfangled product and called it "desecrated vegetables."

The process of preserving food by sealing it in tin cans and heating it to high temperatures was invented by the Frenchman Nicholas Appert around 1800. The French army and navy were the first to adopt canned rations. Other armies adopted "iron rations" as the technology was perfected and industrialized. Quality control was critical, however: inadequate canning led to death by food poisoning for some U.S. soldiers in the Spanish-American War.

Canned corned beef—"bully beef"—became the mainstay of British army rations in World War I, along with the usual dry bread, called "dog biscuits" by the soldiers. "Maconochie rations"—a canned soup of turnips and carrots—provided men in the trenches with some variety, but was unappealing when eaten cold, as it often had to be.

In World War II, the U.S. Army's "C" rations were individual canned items such as beef and beans or corned

beef hash. "K" rations—said to be named after Dr. Ancel Keys, the nutritionist who helped develop them—were complete meals in a water-resistant package, such as a breakfast of canned hash, biscuits, a compressed cereal bar, instant coffee, a fruit bar, and chewing gum. They were intended for short-term use and became monotonous when eaten for days or weeks on end. K rations were discontinued in 1948, although C rations remained in use through the Vietnam War.

The concept of a complete, packaged meal was obviously sound, and armed forces have developed new versions with the food sealed in plastic pouches. The U.S. "Meal, Ready To Eat," or MRE, comes in twenty-four varieties reflecting the range of tastes in the United States, from grilled beefsteak to pasta with alfredo sauce and chicken with Thai sauce. Side dishes such as beans or noodles, fruit, crackers, and dessert round out the meal. The meals provide an average of thirteen hundred calories each. Other armies have similar ration packs, with the British version heavy on tea and puddings while the French version offers duck or salmon appetizers and veal or stewed lamb among the entrees. None of them are particularly popular with the troops, and American soldiers say "MRE" stands for "Meals Rejected by Everyone."

## **MILK.** See **Dairy Products.**

**MILK, HUMAN.** Human milk is a food that evolved to ensure optimal growth, development, and survival of human infants and young children. All female mammals are uniquely equipped to provide species-specific nourishment and immunity through the provision of milk to their newborns.

Lactation refers to the physiological process of producing milk and its removal by an infant. Women produce breast milk as a response to the baby's suckling in an efficient system of supply and demand. Two hormones, prolactin and oxytocin, play important roles in this process. Prolactin is essential for both the initiation and the maintenance of milk production, while oxytocin stimulates milk ejection. Both hormones play complementary roles in breast-feeding, helping the mother relax and easing the infant into sleep. Oxytocin is

particularly intriguing because it controls milk letdown, which can be affected by fear, pain, stress, and anxiety. The oxytocin reflex is more complex than the prolactin reflex. The mother's thoughts and fears may hinder the letdown reflex, and thinking about her baby may trigger the production of oxytocin and milk ejection.

Colostrum, the first milk mothers produce after giving birth, meets all the nutritional needs of the newborn. It has strong antiviral properties, strengthens the newborn's immune system, and acts as a laxative to remove meconium (first feces) from the digestive tract. It is thicker and richer in minerals and protein than mature milk. Colostrum is particularly rich in vitamins E and A. Infants usually consume only a small amount of this first milk. Within one or two days colostrum becomes transitional milk, and the supply increases greatly. The rate at which colostrum changes to mature milk varies from woman to woman, however, mature milk is present within two weeks.

Human milk is a living substance, changing constantly and adapting to meet the changing needs of the infant. For example, it changes from the beginning to the end of a feed. The fore milk has more protein, vitamins, minerals, and water and the hind milk has more fat to signal the end of the feed. Human milk has the highest fat content in the morning and the least at night. It even changes by season, age of the infant, and according to the baby's demand. Human milk reflects the environment, the diet, and the germs of the mother. Ultimately the infant determines the composition of the feed in an interactive process. Although breast pumps are available to many women in urban settings, a breast-feeding infant is the most efficient remover of human milk.

Human milk contains the right mixture of proteins, carbohydrates, fats, vitamins, and minerals to meet all the nutritional needs of infants for about the first six months of life. After the addition of other foods, breast milk continues to offer important nutritional benefits. In May 2001 the World Health Assembly confirmed by unanimous resolution that infants should be exclusively breast-fed for six months and continue to be breast-fed to age two and beyond.

One liter of human milk provides approximately 750 calories and contains 70 grams of carbohydrate, 46 grams of fat, and 13 grams of protein in addition to vitamins and minerals. Breast milk composition is remarkably stable around the world and changes only slightly with different maternal diets and under different environmental conditions. Fat is the most variable component, since maternal diet can modify the fat content of milk. Milk fat provides essential fatty acids and fat-soluble vitamins. The fats in human milk are in forms appropriate for the age of the infant and are readily bioavailable. Lactose is the primary carbohydrate in human milk. Human milk contains both casein and whey protein, but with more whey than casein, human milk is easier for human infants to digest than cow's milk.

The variety of vitamins and minerals produced in breast milk meets the needs of a full-term healthy infant. Water soluble vitamins, however, are influenced by maternal diet. Minerals in breast milk are highest in the first few days after birth. Infants build up iron reserves in utero, and the iron in breast milk is easily absorbed. As a result breast-fed babies are rarely iron deficient. Breast milk contains enough water for a baby, even in hot climates.

The amount of milk produced by a breast-feeding mother varies from around five hundred milliliters a day at day five to around eight hundred milliliters a day at six months, with a slow decline in volume as other foods are added to the diet. Women exhibit differences in the rate of milk synthesis, although the nutritional status of the mother does not significantly affect milk volume or quality. Current research suggests that differences in breast milk storage capacity among women may exist.

Knowledge about the properties of human milk is accumulating rapidly but remained incomplete at the beginning of the twenty-first century. Debates about how human milk is affected by drugs and chemical contaminants center on health consequences for infants and on the ethics of raising concerns when evidence is inconclusive and new mothers are most vulnerable to negative suggestions about the quality of their milk.

Mother's milk has also been recognized as a medium for early flavor experiences, since it is flavored by the mother's ingestion of foods such as garlic, mint, and vanilla. Human milk provides an opportunity for infants to become familiar with the flavors that they will encounter in the household cuisine.

Breast milk is a living substance. It contains living white blood cells that fight infection. Maternal antibodies are passed to the fetus through the placenta before birth and through breast milk after birth, providing temporary immunological protection for newborns. Milk proteins, such as lactoferrin, play an important immunological role, as do enzymes, immunoglobulins, and leukocytes. Human milk is clean and free of bacteria. Unlike artificial milk substitutes, human milk contains nonnutrient substances with the capacity to enhance immunity and destroy pathogens. Human milk has antibacterial, antifungal, and anti-infective properties that have been recognized for centuries. For example, expressed human milk has been used as a folk remedy for conjunctivitis. The protective effect of human milk is strongest for gastroenteritis and respiratory infections. However, the beneficial and protective effects of human milk include lowering the risk of allergies, multiple sclerosis, Crohn's disease, and sudden infant death syndrome (SIDS).

Human milk is seldom considered as a food resource or recorded in food composition tables. It has been suggested that it should be included in the calculations of a country's food supply and food balance sheets. Norway calculated the national production of breast milk to be

Woman nursing her baby. PHOTO BY KARIN GOZZANO. © PICTURE PRESS/CORBIS.

8.2 million kilograms in 1992, valued at U.S. \$410 million (at U.S. \$50 per liter). Norway has subsequently included human milk in calculating national food balance sheets.

It is impossible to put a precise economic value on human milk because it is seldom sold in the marketplace. Attempts to calculate its value include estimating the costs of breast milk substitutes or replacements or more rarely from the price charged for donated breast milk in milk banks. As a unique, incomparable product, its value to human survival is beyond calculation.

**MINERALS.** Living organisms appear to selectively concentrate certain elements from the environment while rejecting others. The adult human body contains approximately thirty-five elements. Four of these (hydrogen, oxygen, carbon, and nitrogen) constitute 99 percent of the atoms in the body. As a comparison, the most abundant elements in the Earth's crust are oxygen (67 percent), silicon (28 percent), and aluminum (8 percent). The remaining 1 percent of the elements in the human body (with the exception of sulfur) are the inorganic or mineral constituents of the body and thus form the ash when the body is "burned." Seven of the remaining elements, sodium, potassium, calcium, magnesium, phosphorus, sulfur, and chloride, together represent about 0.9 percent of the body's weight. The seventeen others make up the remaining 0.1 percent, some of which, but not all, are considered nutritionally essential. These elements appear in the body at measurable concentrations but may not perform an essential biological function. Cadmium is one such example. The newborn infant is virtually free of this element, but gradually accumulates cadmium by ingestion and inhalation, such that over a lifetime an average person living in an industrial society accumulates milligrams of this element. Not only does cadmium appear to serve no essential function in the body, it is also likely to be undesirable and potentially detrimental.

Most experts agree that thirteen mineral elements are nutritionally essential. These are minerals that when deficient consistently result in an impairment of a function that is prevented or cured by supplementation. There still is some question about seven others (Table 1).

The functions of mineral elements are structural, osmotic, catalytic, and signaling. Calcium plays the most obvious role as structural component of bone but also participates in many examples of cell signaling. Sodium, chloride, and potassium constitute the majority of minerals whose function is to maintain osmotic and water balance and membrane electrical potentials. The micro-mineral elements listed in Table 1 have historically been classified as "trace" elements primarily because they occurred at levels below past methods for detection. In general, these minerals function as biocatalysts. Iron is the most prominent example because a deficiency of iron is probably the most common nutritional deficiency on earth (anemia afflicts more than 15 percent of the world's population). Copper and zinc are the prototypical biocatalysts because virtually all of their known functions involve either catalytic or structural roles in many different enzymes. Copper is unique in that all of the known deficiency symptoms in experimental animal models can be explained on the basis of failure of known enzymes. Zinc

deficiency, on the other hand, presents symptoms that are not directly attributable to any of the fifty or more enzymes in which it is found. Selenium, manganese, and molybdenum are also constituents of enzymes. Deficiency symptoms for selenium and manganese have been well characterized but a nutritional deficiency of molybdenum has not been satisfactorily demonstrated. The most compelling reason to include molybdenum among the thirteen nutritionally essential elements is because of its presence (and thus function) in several important enzymes. Some microminerals serve a very narrow range of biological functions. Iodine and cobalt are exclusively constituents of thyroid hormones and vitamin B<sub>12</sub>, respectively. No other role has been identified for these el-

**TABLE 1**

**Known nutritionally essential minerals**

Element	Amount in 70-kg Human (g)	Function
<b>Macrominerals</b>		
Calcium	1,200	Component of bones; signal transduction in hormonal action, muscle contraction, blood clotting; and structural role in proteins
Phosphorus	700	Component of bone Necessary for activation of high energy intermediates
Potassium	240	Osmotic, electrolyte, and water balance
Chloride	120	Osmotic, electrolyte, and water balance
Sodium	120	Osmotic, electrolyte, and water balance
Magnesium	35	Activation of ATPases, kinases, and other enzymes
<b>Microminerals</b>		
Iron	4.0	Catalytic redox reactions, oxygenation, and O <sub>2</sub> -carrying proteins
Zinc	2.0	Catalytic as a Lewis acid and structural function for some metalloenzymes
Copper	0.1	Catalytic in redox reactions some involving iron
Selenium	0.020	Structural and catalytic component of peroxidases, especially glutathione peroxidase. Provides antioxidant protection
Iodine	0.015	Component of thyroid hormones
Molybdenum <sup>a</sup>	0.012	Structural component of enzymes, especially xanthine oxidase and sulfite oxidase
Manganese	0.015	Catalytic role in enzymes involved in cartilage formation
Co <sup>b</sup>	0.001	Structural component of vitamin B <sub>12</sub>

*Abbreviations:* ATPase, adenosine triphosphatase.

<sup>a</sup>Biochemical evidence only that it is essential.

<sup>b</sup>Essential only as a component of vitamin B<sub>12</sub>.

## CALCIUM AND OSTEOPOROSIS

The relationship between dietary calcium and osteoporosis has been studied for many years. Early indications suggested that dietary calcium intake was not correlated with bone density (a indicator of bone strength) or the bone loss that naturally occurs with aging. The complexity of the issue is illustrated by observations that many people consume relatively low calcium diets and yet show little evidence of osteoporosis. The genetic contribution to bone density is well established. Studies of identical twins demonstrate that a considerable proportion of the variation in bone density is attributable to inheritance. Mothers with osteoporosis have daughters (thirty years of age) who possess bone density that is significantly less than age-matched controls. Dietary intervention with calcium has been attempted in many different studies. Those in the past decade suggest that some changes may be effected by increased calcium intake but they are relatively minor and perhaps short-lived. For example, calcium supplements of 500 mg/day over three years were found to affect bone density of some bones significantly only in older women whose habitual calcium intakes were relatively low (<400 mg/day). Supplements had no effect in older women who had higher habitual calcium intakes. This study seemed to indicate that there might be a subset of elderly women who may benefit from increased calcium intake. Because vitamin D has such a critical role in the absorption of calcium, some workers have examined both vitamin D status and calcium supplementation. Overall, the results not surprisingly support the idea that vitamin D may be a limiting factor in the absorption of dietary calcium. Many other dietary variables may also be important in optimizing the effectiveness of dietary calcium. Dietary acidity, which is promoted by protein intake and ameliorated by the consumption of fruits and vegetables, may contribute. Alkaline diets rich in potassium appear to reduce the loss of body calcium and thus preserve bones. Elevated sodium intake also appears to increase urinary calcium losses. Therefore, the development of osteoporosis is unlikely to be a simple matter of too little dietary calcium consumption, especially in the later years of life, but more of an effect of total dietary conditions superimposed on a particular genetic background.

bage appear to contain little oxalate and thus contain calcium that exhibits higher bioavailability than dairy products. Milk and dairy products have relatively high calcium

ements. The remaining mineral elements are those that occur in significant concentrations in the human body and most probably serve an important biological function. However, consistent findings regarding deficiency symptoms and specific biochemical functions have not been reported. Fluorine is a unique example of a mineral that currently has no definitive biological function but because it appears beneficial to dental health, it is a recommended nutrient.

### Calcium and Phosphorus

Approximately 99 and 85 percent of the total calcium and phosphorus, respectively, in the human body are found in bone. Both ions leave the bone and are deposited back each day representing normal metabolic activity or “turnover” of bone. The remaining 1 percent of calcium is found in both extracellular and intracellular pools and is absolutely critical for normal body function such as muscle contraction and nerve activity. Although very rare, a sudden drop in extracellular concentrations of calcium (>50 percent) can lead to an emergency situation such as tetany or convulsions. Nerve cells bathed in hypocalcemic fluid spontaneously “fire,” leading to uncontrolled nerve activation and muscle spasm. The majority of the extracellular calcium is in chemical equilibrium with bone. Approximately 30 percent is under hormonal control by several hormones, parathyroid hormone, vitamin D, and thyrocalcitonin. As a result, the concentration of extracellular calcium is remarkably constant. Blood levels of phosphorus fluctuate much more and appear to be determined in large part by urinary excretion.

The absorption of calcium from the diet is dependent on a number of dietary and physiological factors. Vitamin D is synthesized in skin when exposed to ultraviolet irradiation [290 to 315 nanometers of ultraviolet (UV) light]. Sunscreen lotions [Sun Protection Factor (SPF) 8] can reduce this synthesis as much as 90 percent. Inadequate sunlight exposure was most likely the cause of calcium deficiency rickets observed at the turn of the century in countries at northern latitudes. A change in dietary calcium absorption in humans appears to take several weeks to accomplish but accounts for the ability of humans to tolerate diets that provide relatively little calcium (200 to 400 mg/day). This activation process becomes less potent with age and may account in part for the increased calcium requirements with age.

Dietary factors affecting the absorption of calcium are well known. They include chelating organic acids such as oxalic and phytic acid. The former is the most potent and is responsible for the markedly diminished “availability” of calcium found in spinach. The amount of calcium contained by a food is only an approximation of the amount of calcium that is ultimately “available.” Estimated fractional absorption (percent of intake absorbed into the body) of calcium from these foods ranges from 5 percent for spinach to 61 percent for broccoli. Vegetables of the Brassica family such as broccoli and cab-

content as well as relatively high fractional absorption (30 percent), resulting in the highest amount of calcium per serving. Lactose in milk enhances the absorption of calcium in infants but its effect in adults is less clear. Other dietary factors affect the retention of dietary calcium but have little impact on its absorption. For example, high intakes of either sodium or protein are thought to result in increased urinary losses of calcium. Protein increases renal calcium loss by increasing acid load while sodium increases losses via shared renal transporters. Both of these conditions may affect calcium balance and ultimately the requirements for this nutrient. The bone loss associated with chronic calcium losses or negative calcium balance may ultimately lead to weakened bones or osteoporosis. Calcium supplements may adversely affect the bioavailability of iron.

Calcium deficiency occurs primarily as rickets or osteomalacia in young children. Bones are deformed (bowed legs) and weak due to inadequate calcification of the protein matrix of bone. This deficiency can arise as a result of too little dietary calcium (relatively rare) or inadequate vitamin D synthesis. Historically, the latter has been the major cause brought about primarily because of reduced exposure to sunlight. It is conceivable, however, that dietary factors such as oxalates and cultural customs (clothing) may interact to play a role in the development of rickets especially since recent cases have been reported in areas of the world near the equator where sunlight should not be limiting. Calcium deficiency does not appear to be a primary cause of osteoporosis. This condition is characterized not by inadequate bone mineralization but by a loss of total bone both protein matrix and mineral. Bones weaken and become susceptible to fracture.

### Sodium and Chloride

Total body sodium is approximately one-tenth of that of calcium. One-third of body sodium is found in bone but its metabolic significance is unknown. Sodium and chloride constitute the major cation and anion, respectively, in the extracellular fluid of humans. Sodium is the primary determinant of the osmotic pressure of the extracellular fluid and as such is the main determinant of extracellular fluid volume. The sodium ion concentration changes less than 3 percent day in and day out despite dramatic fluctuations in sodium intake. This is a reflection of a very tightly controlled and highly regulated system to maintain constant osmotic pressure. Through most of human evolution, the availability of dietary salt has been very highly restricted. Much of dietary sodium (and chloride) were derived from sources such as meat and vegetables, which contain very low levels. Consequently, humans and other mammals have evolved physiological mechanisms that permit sodium conservation under extreme conditions. This physiological conservation system comprised of pressure receptors, renal renin, lung angiotensinogen, adrenal aldosterone, and vasopressin all makes dietary requirements extremely diffi-

cult to assess. For example, the Yanomamo Indians in Northern Brazil have been found to excrete as little as 1 mEq/day of sodium (Na) per day. This reflects a dietary consumption of approximately 60 mg salt per day (over 100 times less than that which is normally consumed in Western populations). At the other extreme are the northern Japanese, who consume nearly 26 grams of salt each day. These regions of Japan have unusually high incidences of cerebral hemorrhage, most likely related to the high incidence of hypertension. Other areas of the world such as Northern Europe and the United States consume approximately 10 g/day or less of salt. The sodium and potassium contents of some selected foods are shown in Figure 1. It is apparent that many "unprocessed" foods contain very little sodium. Estimates of sodium intake suggest that over 85 percent of the sodium consumed in Western diets is sodium added during processing. This is clearly illustrated by the progressively higher sodium content of peas (fresh, frozen, and canned) and perhaps more important, the dramatic reduction in potassium content. The net result is a reversal of the naturally low sodium to potassium ratio found in all fresh plants.

A deficiency of sodium normally does not occur even in areas where salt is scarce. The abnormal loss of sodium and other electrolytes, however, could occur under conditions of extreme sweat loss, chronic diarrhea and vomiting, or renal disease, all of which produce an inability to retain sodium. Acute episodes of diarrhea or vomiting resulting in a loss of 5 percent of body weight could lead to shock. The most important therapy under these circumstances is to restore sodium and water or circulatory volume. Chloride deficiency has been reported in infants consuming low-sodium chloride formulas. They show signs of metabolic alkalosis, dehydration, anorexia, and growth failure. Potassium depletion most notably affects cardiac function where either elevations or reductions in serum potassium can cause arrhythmias.

FIGURE 1

## Magnesium

Magnesium is an important intracellular ion involved in many enzymatic reactions of food oxidation and cell constituent synthesis. Approximately 60 percent of total body magnesium is found in bone, where approximately half can be released during bone resorption. Magnesium food sources are widely distributed in plant and animal products with the highest content found in whole grains and green (high chlorophyll) leafy vegetables. Refining wheat with the removal of the germ and outer layers may remove nearly 80 percent of the magnesium from wheat. Meats and most fruits and vegetables are poor sources of magnesium. The absorption of magnesium appears to be unrelated to the absorption of calcium (that is, is independent of vitamin D) and is relatively unaffected by food constituents. Phytate and phosphates, however, may adversely affect magnesium availability by forming insoluble products although their practical significance is unclear. Experimental magnesium deficiency has been produced in humans. Urinary magnesium drops virtually to zero while plasma levels are relatively well preserved. The change in urinary excretion reflects a "urinary threshold" for magnesium. After continued deficiency, however, neuromuscular activity is affected, ultimately leading to tremors and convulsions. Serum and urinary calcium levels are profoundly reduced and not restored by parathyroid hormone administration. It was concluded that magnesium is essential for the mobilization of calcium from bone. A deficiency of magnesium under normal conditions is unlikely but may occur with the presence of other illnesses such as alcoholism or renal disease.

## Iron

Over 65 percent of body iron is found in hemoglobin, the respiratory pigment used to transport oxygen within and between tissues. One-third of body iron is a "storage" form that can be mobilized during times of need. The amount of "storage" iron may vary greatly with age and gender. Food sources of iron are complicated by numerous factors that affect the bioavailability of dietary iron. Non-heme sources of iron are found in plant and vegetable products and the absorption from these sources (versus heme found in meat products) is generally lower and influenced to a greater extent by total diet composition. Vitamin C is probably the most significant enhancer of non-heme iron absorption, while plant phenolics such as tannins found in teas and phytates found in cereals are some of the most potent inhibitors. None of these factors, however, affect the absorption of heme iron found in meats. Iron status can markedly affect the amount of iron absorbed from a meal—low status increases iron absorption. The effect is most pronounced for non-heme iron, changing over fourfold compared to 50 percent for heme iron. Although iron status can influence absorption, the most important determinant of iron availability is the composition of the diet. It is clear that non-heme iron absorption is markedly affected by the characteristics of the food with which it is eaten and that there are

## SODIUM AND POTASSIUM

In the early 1950s, scientists found that experimental animals could be selected genetically to be susceptible to dietary salt-induced hypertension. Lewis K. Dahl and colleagues established a genetic strain of rat that was sensitive to high dietary salt. These rats showed remarkably elevated blood pressure when dietary salt was increased approximately ten times above normal. The rats' kidneys appeared to have a genetically programmed sensitivity to salt-induced hypertension. However, in the absence of high dietary salt, these animals were normal. Dietary potassium was also recognized as an important factor since high concentrations could ameliorate the effect of sodium chloride. Establishing a direct link between high dietary salt intake and hypertension in humans has been difficult to prove. The problem has been that not all individuals within a population are equally sensitive. Much evidence has come from studies of populations with widely differing salt intake. Populations whose sodium intake is low (less than 100 milligrams of salt) do not appear to develop elevated blood pressure with age. Those whose intake is relatively high do show increased blood pressure with age and evidence of increased incidence of essential hypertension. Recent studies with nonhuman primates have clearly shown that changes in salt intake alone are sufficient to induce changes in blood pressure. Many other studies suggest that lower potassium intake may also be important in the etiology of elevated blood pressure. Certain individuals may be more susceptible or sensitive to sodium-induced changes in blood pressure (similar to experimental animals). All of the known mutations resulting in a phenotype of hypertension involve some aspect of sodium renal excretion and/or retention. It is likely, then, that genetic sodium sensitivity will be a prerequisite to an environmentally induced development of hypertension.

clear differences in the nature of absorption of heme and non-heme iron. Iron deficiency is seldom related to iron intake per se. Major causes of anemia (too little hemoglobin) include blood loss and/or diets containing either no enhancers (such as meat or ascorbic acid) or high levels of inhibitors. Infection can also change iron metabolism significantly such that much of the anemia in the world is due to chronic infection. The losses for iron for both men and women are known precisely but the amount of dietary iron requirement depends on the overall diet.

## Zinc

Zinc is present in all tissues and performs both structural and catalytic functions in many different enzymes. Unfortunately, changes in the activities of these enzymes are not sufficient to explain the pathological effects of experimental zinc deficiency. Experimental animals refuse to eat experimental diets that are very low in zinc. Human zinc deficiency was demonstrated nearly two decades ago in the United States. Young children from 6 months to 5 years of age showed low amounts of zinc in the hair relative to other groups. Hair zinc and taste acuity were restored after three to five months of zinc supplementation. Earlier studies also revealed zinc deficiency in regions of Iran and Egypt. It is very difficult to assess zinc status in humans. Serum zinc is not adequate to assess nutritional status. In experimental situations, serum zinc falls remarkably (>50 percent) following a low zinc intake without immediate (or apparent) ill effects. In 1974, a Recommended Dietary Allowance (RDA) of 15 mg/day was established for zinc. (It was not until 1974 that we had enough information to estimate an RDA for zinc, at which time the value was established at 15 mg. The RDA presented in 1989 gives 15 mg per day for adults. The 2001 Institute of Medicine value is 11 mg per day.) Approximately 70 percent of zinc consumed by most people is derived from animal products. Cereals contain appreciable zinc but the availability varies considerably. Several plant compounds interfere with the absorption of zinc. The most prominent of these is phytates (inositol hexa- and pentaphosphate). These inhibitors most likely contribute to the natural incidence of dietary zinc deficiency observed in humans.

## Copper

Although the importance of copper deficiency in animals has been recognized since the 1930s, it is still not possible to establish an RDA for copper in humans because of the uncertainty regarding the quantitative requirements. There is no doubt that copper is an essential nutrient for humans. Current estimates of the minimum copper requirement are between 0.4 and 0.8 mg/day. Copper is critical for the function of several enzymes, especially blood ceruloplasmin. The activity of this enzyme in blood falls dramatically in experimental animals soon after giving copper-deficient diets and is thought to be a good indicator of copper depletion even in humans. Ceruloplasmin is essential for iron absorption (it catalyzes the oxidation of  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$  required for binding of iron to the blood transport protein, transferrin) and explains the anemia observed in copper deficiency. In contrast to zinc, all of the symptoms of a copper deficiency under experimental conditions can be explained by changes in various enzymes that require copper. Two inherited diseases associated with abnormal copper metabolism have been observed—one (Menkes' disease) is associated with copper deficiency, while the other (Wilson's disease) is a disease of excessive copper accumulation. Excessive intake of zinc can precipitate a copper deficiency. An example

of zinc-induced copper deficiency has been reported in humans and is attributed to a reduction in the absorption of copper. Excessive zinc may induce intestinal proteins that bind copper and thereby prevent its transfer from the intestine into the body.

## Iodine

Approximately 80 percent of total body iodine (20 milligrams) is found in the thyroid gland. All of the iodine that leaves this gland does so as a component of the thyroid hormones—thyroxine and triiodothyronine. In fact, all of the functional significance of iodine is as a component of these hormones. Iodine deficiency represents the most common cause of preventable mental deficits in the world's population. Since most of the world's iodine is found in the oceans, coastal areas are not deficient. However, mountainous areas such as the Himalayas, European Alps, and the mountains of China, as well as the flooded river valleys of Asia, areas where leaching of iodine from soils has occurred for eons, produce iodine-deficient crops and plants. Iodine deficiency during pregnancy causes cretinism, a diet-related birth defect that is characterized by permanent mental retardation and severe growth stunting. In young children and adults, iodine deficiency results in enlarged thyroid glands or goiter. Although various foods such as cassava, cabbage, and turnips contain goitrogens, substances that interfere with iodine metabolism, their practical significance is not clear. Cassava, the dietary staple in regions of Africa and other areas, may be the exception, especially when not well cooked. The cyanide released by the ingestion of this plant is transformed and ultimately leads to an inhibition of the uptake of iodine by the thyroid. Goiter was once common in areas of the United States near the Great Lakes and westward to Washington State, but the introduction of iodized salt almost completely eliminated goiter in these areas by the 1950s. The minimum requirement for iodine to prevent goiter is approximately 1  $\mu\text{g}/\text{kg}/\text{day}$  whereas the recommended intake is nearly twice this amount.

## Selenium

Although selenium was first recognized as a toxic trace element for livestock, it is now clear that selenium is an essential nutrient for all animals. During the 1930s, livestock grazing in parts of the Great Plains of North America were found to contract a disease characterized by hair loss, lameness, and death by starvation. The cause of this disease was excess selenium obtained from the plants grown in soils containing high selenium concentration. In fact, selenium, more than any other essential trace element, varies greatly in its concentration in soils throughout the world. Plants accumulate selenium from soils but are not thought to require selenium for growth. Although human toxicity was not observed in affected regions in the United States, endemic selenium poisoning has been observed in high-selenium regions of China where the symptoms included loss of hair and nails. China also possesses regions of very

low selenium where, in fact, humans have been diagnosed with selenium deficiency—Keshan disease (cardiomyopathy) and Keshan–Beck disease (degenerative joint disease). Although other factors may be involved, selenium deficiency is clearly a predisposing factor. Selenium functions as part of several important enzymes. The most prominent is a soluble enzyme, glutathione peroxidase, whose function is to reduce hydrogen peroxide and organic (lipid) peroxides, thus preventing the oxidative destruction of cell membranes. Selenium is incorporated into the enzyme as the amino acid selenocysteine by reactions that are unique to selenium. Together with vitamin E, selenium, as a structural component of glutathione peroxidase, forms an antioxidant defense against oxidative stress. The requirement for selenium has been estimated by various methods. On the basis of intakes in regions of China with and without deficiency disease, approximately 20  $\mu\text{g}/\text{day}$  is considered an adequate amount to prevent deficiency. The estimated safe and adequate selenium intake suggested by the U.S. National Research Council ranged from 50 to 200  $\mu\text{g}/\text{day}$  in 1980. An amount to maintain the highest serum glutathione peroxidase activity appears to be 70 and 55  $\mu\text{g}/\text{day}$  for an average man or woman, respectively, which became the Recommended Dietary Allowance (RDA) in 1989. In 1996, the World Health Organization recommended 40 and 30  $\mu\text{g}/\text{day}$  for men and women, respectively. Intakes greater than 400  $\mu\text{g}/\text{day}$  are considered to be the maximum safe level. Selenium is thus an example of a nutrient that possesses a relatively narrow range of intakes that are safe and that meet requirements.

### **Manganese**

Normal body content of manganese is very low—approximately 15 milligrams or very similar to iodine. In contrast to iodine, manganese deficiency has not been observed in humans but has occurred naturally in chickens and experimentally in many other species. Manganese is required by several enzymes, which may or may not be involved in the symptoms of a manganese deficiency. Symptoms include impaired growth, skeletal abnormalities, and defects in lipid and carbohydrate metabolism. The role of manganese in the synthesis of the mucopolysaccharide component of bone and cartilage is the most crucial whereas mineralization of bone appears to be independent of manganese. Excessive manganese will interfere with iron absorption. Under conditions of iron deficiency, manganese absorption is increased. Both iron and manganese appear to share a common site for absorption. The recommendations for manganese intake are based on estimates of normal dietary intakes of 2 to 5 mg/day. This amount is thought to be sufficient to replace the 50 percent of body manganese that is lost every 3 to 10 weeks.

### **Chromium**

Chromium is one of the most intriguing and potentially important trace elements because it appears to influence

the action of a critical hormone, insulin. Unfortunately, the definitive role of chromium in this regard awaits further study. Decreased sensitivity of peripheral tissues to insulin appears to be the primary biochemical lesion in experimental chromium deficiency. Impaired glucose tolerance has been attributed to chromium deficiency in several experimental models. Also, several patients receiving total parenteral nutrition have responded to chromium supplementation in the predicted manner, that is, improved glucose tolerance. These findings have established chromium as an essential nutrient for humans but the specific deficiency symptoms in those who receive enteral feeding have not emerged. Overt chromium deficiency is very unlikely under normal conditions due to the small amounts of chromium needed. Moreover, a marginal deficiency is very difficult to identify due to the lack of reliable markers for diagnoses concerning chromium. Currently, there is little or no evidence that chromium supplements are either warranted or effective. Even the recommended intakes for adults (50 to 200  $\mu\text{g}/\text{day}$ ) are uncertain due to the lack of reliable methods for assessment.

### **Fluoride**

Fluoride is not generally considered to be an essential element for humans. It is, however, considered beneficial in that normal intakes appear to reduce the incidence of dental caries. The mechanism of this benefit is thought to be due to incorporation of fluoride into the mineral matrix of tooth enamel, thus producing a more resistant mineral apatite crystal. Over 99 percent of the fluoride found in the body is found in bones and teeth as a component of this mineral apatite crystal. An unusually high intake of fluoride causes permanently discolored or mottled teeth, a condition identified in children drinking water with 2 to 3 parts of fluoride per million. The level of fluoride commonly maintained in municipal water supplies is 1 part per million.

### **Silicon and Nickel**

Silicon is the most abundant mineral in the Earth's crust. It is thus surprising that a need for silicon in biological systems has not been more prominent. Limited research conducted since 1974 has indicated a role for silicon in the development of mature bones in chickens and rats. A human requirement has not been established but estimates in the range of 10 to 20 mg/day have been suggested. Most likely intakes of this magnitude occur under normal conditions. Nickel deficiency has been experimentally produced in several species. Growth depression and changes in iron metabolism have been described. Nickel has been discovered in the enzyme urease from bacteria, fungi, yeasts, algae, plants, and invertebrates. Many other enzymes exist for which nickel is apparently a component. Thus, it is likely that nickel plays an essential functional role in higher organisms, including humans.

## Molybdenum

Molybdenum is an essential component of at least three important enzymes found in animals and humans. A deficiency of one of these enzymes, sulfite oxidase, can have severe consequences—seizures and severe mental retardation in infancy. This deficiency has arisen in patients with genetic mutations in cofactor synthesis but not as a primary molybdenum deficiency. The dietary requirements of molybdenum cannot be given, or even approximated, for any animal species including humans. A deficiency of molybdenum has not been observed under natural conditions for any species. Despite this, the biochemical role of molybdenum as a component of several enzymes establishes it as an essential nutrient for humans.

**MOLLUSKS.** Mollusks exist in diverse forms, and although a mollusk is easily recognizable as such to a scientist who studies them, there is no obvious relationship between, say, an oyster and a flying squid. In fact people with no specialist knowledge are more likely to think of them as comprising separate groups: the gastropods (single shells), such as abalone or whelk, inhabiting single shells; the bivalves, such as clams and oysters, which have double shells; and the cephalopods (the name literally means "head-feet," referring to their strange configuration), which include cuttlefish, squid, and octopus.

The number of species in each of these groups is huge. The biodiversity of mollusks is far greater than that of fish and is exceeded only by the vast armies of insects. Three-quarters of the species of mollusks are gastropods, the category that is on the whole of least interest to human consumers. Next come bivalves. Third in numbers but greatest in size are the cephalopods. In relation to the human diet, the bivalves were probably the most important in prehistoric times, because most of them do not move around and many of them exist in the intertidal zones, or in very shallow waters, and are therefore easily gathered. Excavations at Skara Bray in the Shetlands have uncovered huge middens (a term used by archaeologists for a prehistoric refuse-heap of shells and bones) of bivalve shells, indicating very heavy consumption of them during the Stone Age. Evidence from coastal areas in many other parts of the world, including Japan, confirms this. Although consumption of clams and oysters and mussels and scallops is considerable today, especially in Europe and North America, it is the cephalopods that have become most important globally. The fishery for squid is conducted on a huge scale, and squid are a major source of protein for people in the Indo-Pacific area, as well as elsewhere.

In very ancient times, only people living near the coasts could benefit from eating marine mollusks ("marine" is specified in order to distinguish this group from terrestrial mollusks such as edible snails). Even if transport had been available to take mollusks far inland to

other communities, the perishability of most of them (still a major factor today, despite the advent of refrigeration and freezing) would have ruled out such traffic. However, there may have been some exceptions. Preservation by drying is a method that is not applicable to many mollusks but can be used for cephalopods. The Greek practice of drying octopus is probably of great antiquity.

In developed countries where modern techniques are available, the transport of even delicate mollusks such as oysters (which have to be kept alive until consumption) is well assured and there is hardly anywhere in these countries where customers cannot enjoy the full range of mollusks. Availability accounts for increased demand, as does the dramatic increase in the size of human populations. However, the factor that has done most to make mollusks almost ubiquitous on dining tables is undoubtedly the great advances made in fishing techniques since medieval times. The huge resources of oceanic squid were simply not accessible in earlier times, whereas today there are few parts of any of the oceans where squid are relatively safe from capture. The sophistication of the equipment used by the vessels that fish for them, especially those from Japan, is extraordinary.

Before considering the three groups of mollusks in more detail, there is one question of nomenclature to consider, and another of classification.

The term "shellfish" is defined in the *New Shorter Oxford English Dictionary* as "any aquatic invertebrate animal whose outer covering is a shell, usually a mollusc (as an oyster, a winkle, a mussel, etc.) or a crustacean (as a crab, a prawn, a shrimp, etc.), especially one regarded as edible." The term is commonly used for crustaceans and for any mollusk living in an exterior shell. Thus it would apply to the single shells and bivalves but not to cephalopods, with one exception: the so-called chambered nautilus shells, which count as cephalopods but do inhabit shells. A few species of nautilus have value as food in the Indo-Pacific area. It is also relevant to point out that the other cephalopods tend to have what might be called "internal" shells, for example, the "cuttlebone" found in the cuttlefish. These constitute traces of external shells that have disappeared in the course of evolution. The chambered nautilus is, so to speak, poised to take a further step in evolution and abandon its shell, whereupon it would bear some resemblance to a small squid. The question of classification referred to above is this: does the term mollusk include miscellaneous sea creatures such as the sea cucumbers and sea anemones that are eaten in some parts of the world and that are neither fish nor crustaceans but, owing to their general appearance, might be taken to be mollusks? The answer is no; they belong to separate orders. For example, the sea cucumbers belong to the order Holothurian. Furthermore, if a creature is not a fish but does have a shell, must it be either a crustacean or a mollusk? Again the answer is negative. The sea urchin, whose ovaries are a prized delicacy, has what would normally be called a shell (cov-

Seafood merchant selling octopus in Tokyo, 1986. © ROBERT HOLMES/CORBIS.

ered usually with spines to repel predators), but it belongs to the phylum Echinodermata.

Having thus cleared what might otherwise be muddy waters for some readers it is time to look more closely at the three main groups of edible mollusks.

### Single Shells

The gastropods, or single shell mollusks, have contributed less to human nutrition than either the bivalves or the cephalopods. This is not because the single shells are too small. Some, such as whelks, attain a considerable size, up to 90 cm (35 inches) in the case of the species *Melongena pugilina*, which is eaten in Malaysia and the Philippines. Large whelk, often called conch, are eaten in the Caribbean, where they are known locally as *lambis* or *lambie*. One speciality is the conch stew of Martinique and Guadeloupe while another is soused conch, (*lambie souse*). In *Life and Food*, Cristine Mackie describes this specialty as well as other food of the region, and makes one particularly interesting observation. She believes that the native inhabitants, who are known to have

consumed conch in large quantities and whose experience preparing it stretches back over many centuries, probably showed early white settlers how to extract the meat and clean it, a special skill requiring instruction.

Even very small single shells are eaten, for example, the little top-shell of the Mediterranean (*Monodonta turbinata*, of the family Trochidae) or the equally small periwinkle (*Littorina littorea*, family Lacunidae), known locally as winkles and found on North Atlantic shores, both east and west, but mostly appreciated in Europe. In general, however, the appetite for single shells has diminished in many parts of the world, largely because they are fished locally and few of the edible species have more than minimal gastronomic merit.

Nevertheless, one family among the single shells, Haliotidae, to which the abalone belong, certainly does merit attention for human consumption. There are species all round the world. In California, for example, the red abalone (*H. rufescens*), is probably the best known although *H. tuberculata* has been famous since classical times in the Mediterranean and on the European Atlantic coast as far north as the Channel Islands (where it is known as ormer in English and *ormeau* in French). However, supplies are not abundant. Indeed, along much of the northwest coast of the United States the fishery is either closed outright or subject to severe restrictions. In Japan there is a tradition that stretches back to antiquity of husband-and-wife teams fishing for abalone; the wife dives while the husband tends the boat and the lifeline. Depending on the quality of the various species, the Japanese may eat them raw, diced and iced and furnished with a dipping sauce, or grilled and steamed. Generally, abalone is tough and must be tenderized before being cooked.

Although some abalone can reach a size of up to 25 cm (10–11 in.), they may be regarded as a sophisticated descendant of the ordinary limpet. Limpets, seen clinging tenaciously to seaside rocks, are much smaller and biologically less complicated creatures, but are edible and utilized in interesting local recipes; for example, in some parts of Scotland people were known to mix limpet juice with oatmeal.

### Bivalves

The aristocrat of bivalves, in the western world, is the oyster. This is odd because in the nineteenth century oysters were so plentiful and cheap that they were considered to be a food of the poor. Today virtually all the oysters brought to market are cultured. In France especially, there are complex systems followed by oyster farmers, from the initial seeding (planting on special tiles) of the spat of existing oysters through various changes of environment designed to afford protection from predators and to encourage growth. Oysters thrive in the “parks” created for them, and are carefully graded before being transported live to markets. The district of Marennes-Oléron accounts for well over half the French

production, but other place names such as Arcachon indicate other famous oyster areas. In England the oysters of Colchester in Essex and of Whitstable in Kent were once of great renown, but nowadays most of the oysters reaching British markets come from the south of Ireland.

What is said above relates in part to the European oyster, *Ostrea edulis*. However, populations of this species have been very seriously depleted, in some places to vanishing point, and 90 percent of the oysters now consumed in Europe belong to the species *Crassostrea angulata*, popularly known as the Portuguese oyster. It is a native of Portugal and Spain and also known in the Indo-Pacific as the Giant Pacific oyster.

In North America, the American oyster, *Crassostrea virginica*, holds sway. Like the Portuguese, it is larger than the European. American oysters are marketed under many names, indicating the place of origin, for example, Cape oysters from Cape Cod (notably Wellfleet and Chatham); Long Island (Bluepoint, Gardiners Bay), and the Chesapeake Bay area (Chincoteague Bay). Of the other American species of oyster, the best is probably the Olympia oyster, a subspecies of the Californian oyster, *Ostrea lurida*.

Australasian oysters include the Sydney rock oyster, *Crassostrea commercialis*, which is perhaps the most esteemed of all seafoods for Australians.

Whereas oysters are always visible, many bivalves are not. They burrow into the sand and all one can see is perhaps their “siphon” protruding, or a little hole left by the siphon. Some species are remarkably adept at burying themselves quickly and deeply. The razor shells (so-called because they resemble old cut-throat razors) are among the champions in this art. They are known in Orkney as “spoots,” and “spooting” by hand is a pastime that calls for great expertise. There are many other clams in both hemispheres that live closer to the surface of the sand and are gathered more easily. Consumption is highest in North America, where they play a leading role in the traditional clambake, which is an important feature of the seafood cultures of many coastal areas, especially New England. Kathy Neustadt explains the cultural and social importance of clams in *We Gather Together: Food and Festival in American Life*. A purely practical description is found in the classic cookbook by Mrs. Lincoln, *Mrs. Lincoln's Boston Cookbook* (1891).

Mussels dominate the European market, at least in terms of quantities sold. The waters surrounding Galicia in the north of Spain include bays that are ideal for the culture of mussels on big ropes suspended from the surface of the sea. By the end of the twentieth century, Spanish exports of mussels had grown to such an extent that they dominated the market, although there is a smaller but substantial industry in the Netherlands, providing mussels mainly for consumption in Belgium. Mussels with french fries (*moules et frites*) is counted by some as the national dish of the Belgians; it enjoys popularity

there which is without a parallel anywhere else in the world. However, there are many other ways of preparing mussels including the famous French dish *moules à la marinière* (mussels steamed open in a large covered pot with chopped shallots, herbs, white wine, vinegar, and butter). Mussels are also a useful ingredient in seafood stews and kindred dishes. Mussels can be steamed or fried, and it is also possible to dry mussels (after a boiling). In Thailand dried mussels are coated with sugar and then fried, producing an intriguing dish that might seem strange to western palates.

Those familiar with Irish culture know the song about Sweet Molly Malone who, in the streets of Dublin (where she is commemorated by a charming statue), would cry her wares: “Cockles and mussels alive alive o’.” Cockles constitute a large and important group of bivalves, with the European *Cerastoderma edule* being the most important. In some places it is quite remarkably abundant; densities of over ten thousand individuals per square meter have been recorded. With a maximum measurement around 6 cm (2 inches), this is not the largest cockle; that distinction goes to the spiny cockle of the Mediterranean, *Acanthocardia aculeata*, whose body inside the shell is blood red, may reach 10 cm (4 in.). One of the cockles of the Pacific coast of North America, *Clino-cardium nuttalli*, may be slightly larger still. Cockles resemble clams in their burrowing down into the sand.

Like oysters, mussels are visible wherever they grow. Another visible bivalve of gastronomic importance is the scallop, who for most of its life is not attached to anything but swims freely, using the rapid opening and shutting of its two shells as a means of propulsion. The muscle connecting the two shells is therefore particularly large and strong, a feature welcome to consumers since this white muscle is the principal edible part. (The orange-yellow coral is also eaten and the “mantle” or “frill” more rarely.)

Of the many species, *Pecten maximus*, the Great Scallop, and *Pecten jacobaeus*, the Pilgrim scallop, are the best known in Europe. The former may measure 16 cm (6 in.) across, while the latter is smaller. It is, however, the latter which has a special religious significance, since its shell has for very many centuries been the badge worn by pilgrims to the shrine of St. James at Santiago de Compostela in Galicia. Indeed, the French name Coquille Saint-Jacques is sometimes applied to scallops in a more general way, as in the famous dish *Coquilles Saint-Jacques à la provençale*. Besides being a badge for pilgrims, scallops have a cultural significance in many other contexts, a point that is well brought out by Cox (1957).

The so-called bay scallop, *Argopecten irradians*, is the common commercial scallop of the American Atlantic coast. Its muscle, which is usually the only part sold, is a great delicacy. If really fresh, it may be eaten raw, flavored by its own juices. There is also a growing North American fishery for the Atlantic deep-sea scallop, *Placopecten magellanicus*.

The scallop is well provided with eyes. About fifty of these, green ringed prettily with blue, are set in the frill. These do not show the scallops where they are going, since they are necessarily always going in the other direction, but they do warn them of any danger approaching from behind.

Edible bivalves can be very small, such as the little wedge shells. Other bivalves, of which parts only can be eaten, are huge, notably the giant clam of the Indo-Pacific, *Tridacna gigas*, which can measure 1 meter (40 in.) across and weigh several hundred kilos; the shells from one of these can provide two washbasins or church fountains.

Because bivalves have two shells joined together, they symbolize in Chinese and other cultures a married couple. Although many of them are plain in color, some have very striking patterns on the outside of their shells, such as zig-zag markings.

### Cephalopods

A comprehensive reference book published by the Food and Agriculture Organization, or FAO (by Clyde F. E. Roper, Michael J. Sweeney, and Cornelia E. Nauen), provides a good overview of the cephalopod fisheries, offering information on over two hundred species. Although confined to species “of interest to fisheries,” this work does include some which are utilized at the subsistence and artisanal levels only and some which at present have only a potential value in commerce. A few cephalopods are of outstanding importance in commerce: squid of the genus *Loligo* and *Todarodes pacificus*, the Japanese flying squid, are outstanding examples. Squid account for approximately 70 percent of the world catch, while cuttlefish represent between 10 and 15 percent and octopus between 10 and 20 percent.

The “flying squid” do not really fly but can propel themselves out of the water and glide. They have longer and thinner bodies than other squid, which makes them less suitable for being stuffed. All squid have eight short and two long tentacles. The long ones can be shot out to catch prey. The size of adult squid varies greatly from little more than 20 cm (8 in.) to 20 m (67 ft.) overall.

Cuttlefish also have eight short and two long tentacles, but they are more compact than the squids, having a broader body. Their “ink,” like that of squid, is contained in sacs but may be expelled in large clouds to facilitate evasive action. Cuttlefish ink was used historically to make the color sepia, and the Chinese have called the cuttlefish “the clerk of the sea-gods,” in a reference to the ink (Read, 1939). Generally, Chinese names for cephalopods are far more descriptive than English ones. For example, the Chinese call one small squid “shallow water soft fish,” indicating where it is found, while the cuttlefish may be known as “tiger-blotched black thief.” This highly specific nomenclature is in line with the fact that cephalopods play a larger part in food culture in China than in most other countries. While it is true that

cephalopods, especially squid, have now reached the market in almost all important countries of the world, it is only in certain regions, including the whole of the Mediterranean, that there is a long tradition of eating them. Full acceptance in North America is still to come, although the influence of Americans from a Mediterranean background has done much to show the way to others.

Those repelled by the appearance of cephalopods might be especially upset by the octopus. The name octopus refers to its eight arms, each armed with suckers for grasping prey. The best octopus for eating have arms with a twin row of suckers on each. The most common octopus of the Mediterranean, *Octopus vulgaris*, has been important since classical times in many of the cultures of the region, and has figured frequently in art, as on Greek vases of the late classical period.

The flesh of the octopus is notorious for being tough and requiring treatment to soften it before cooking. This does not apply to tiny baby octopus, but the larger specimens are beaten against rocks by fishermen, or struck with mallets, to tenderize them. Delicious and flavorful octopus dishes include the Spanish *pulpos con papas*, the

French *poulpe à la niçoise*, and the Neapolitan *polpetielli alla Luciana*.

In connection with the last-named dish, a Neapolitan author, Signora Jeanne Carola Francesconi (1965), has given a vivid description of methods of fishing based on the fact that the true octopus (the kind with two rows of suckers on each arm) is especially attracted by the color white. Thus a piece of white rag may be placed in the center of a five-pronged hook and lowered down to ensnare the octopus. "It is also fished with a pottery amphora (called a 'mummarella') which is likewise painted white and contains white stones; this is lowered to the bottom on the end of a rope, near a rock. The 'true' octopus, if he sees it, will empty the pebbles out and instal himself inside as though in a nest. The fisherman, alerted by seeing the white pebbles scattered outside the amphora, pulls it up and thus catches the octopus." Although the octopus is thus outwitted, it is fair to add that of all mollusks it possesses the most intelligence. Experiments conducted at an aquarium in Naples established that an octopus is capable of learning, for example, how to move from one tank to another, when there are several apparent exits of which only one allows passage.

**MOOD.** Eating and drinking affect, sometimes markedly, people's moods. The interaction runs the other way, too, so that depressed, manic, or anxious states lower or sometimes heighten appetite, or a particular mood can affect food choices. The connections between food and mood have implications for advertisers of snack foods, for those seeking to lift their spirits through binge eating or drinking, and for gourmards planning successful dinners.

Alcohol can manipulate mood by affecting the release of certain chemicals in the brain called neurotransmitters. The caffeine in coffee and other drinks is another stimulant whose overuse has detrimental health effects. Herbs have a range of medical effects, and some mushrooms are mind-altering. But while a variety of foods contain chemicals with known psychotropic properties, they are generally in such minuscule quantities as to have little discernible effect on human consumers.

More noticeable changes occur through a combination of cognitive, sensory, cultural, social, and environmental factors. For example, chocolate contains chemicals that alter mood, such as caffeine, theobromine, and phenylethylamine, in quantities too small to account for the cravings of so-called "chocoholics." Instead, people value chocolate's sweet taste and voluptuousness, be-

cause it melts just below body temperature, and so coats the tongue. The pleasurable sensations release chemicals, called opioid peptides, in the brain that lift mood. Chocolate has long been advertised as a luxury, and parents and others choose it to reward good behavior. All these uses reinforce chocolate's reputation as an "indulgence," "temptation," and even "sin."

Likewise, some acclaimed aphrodisiacs contain traces of chemicals that might stimulate sexual activity (suggestions include the zinc in oysters and a chemical related to the male hormone testosterone in truffles). But the pleasures associated with their consumption can be more striking than any actual chemical effect. One of these foods is extraordinarily slippery and the other headily aromatic. In addition, the seducer may offer them in a mood-inducing setting, such as a comfortable, candlelit room filled with "mood music."

Even the psychological response to alcohol is dependent on numerous factors, not the least of which are the experience and existing mood of the drinker, the setting, and the organoleptic or sense-stimulating properties of, perhaps, a fine wine. As such, the same drink can make people feel euphoric, merry, riotous, bored, or maudlin. Some researchers have found that high-carbohydrate foods reduce tension and cheer people up, while high fat foods have the opposite effect, but this theory is not supported by the English writer Charles Lamb's paean to pork crackling, "Dissertation on Roast Pig," published in the 1820s. With mock seriousness, Lamb attributes the discovery of cooking to the "oleaginous . . . ambrosian" deliciousness of pork fat.

An angry remark, an overlong gap between courses, a disturbing location, or the overdoing of food and drink can destroy the pleasant mood of a meal. But an enticing plate of food placed in front of a willing guest can be entrancing. An experienced waiter can guide indecisive diners, turning their entire evening around. The right foods, company, and circumstances cast a positive spell, whether of gaiety, carefreeness, reverie, or joy.

The New Testament refers often to "joy" (in Greek, *charà*), frequently experienced at meals. A blissful state is encapsulated in many of the brief *Rubáiyát* of Omar Khayyám, written nearly one thousand years ago, and most famously in Edward FitzGerald's translation: "Here with a Loaf of Bread beneath the Bough, / A Flask of Wine, a Book of Verse—and Thou."

Jean-Anthelme Brillat-Savarin analyzed the special mood attainable at the table in his gastronomical classic, *The Physiology of Taste* (published in 1826). Reporting on a lifetime of dinners, closely observed, he consistently suggests that a meal's greatness depends less on particular foods than on achieving an overall mood. His term, *le plaisir de la table*, has often been translated in the plural as the "pleasures of the table." However, the book's "Meditation 14" discusses a composite "table-pleasure" that one might call "mood." Table-pleasure is "the

reflective sensation" (*la sensation réfléchie*) generated by the thoughtful assembling of foods and people in an appropriate setting. This manifold pleasure of the table is known only to the human race and is largely independent of the drive for food, he writes.

While Brillat-Savarin precludes from table-pleasure ravishments, ecstasies, or transports, the experience, as he sees it, gains in duration what it loses in intensity. Physically, a diner's brain awakens, face grows animated, color heightens, eyes shine, and a "gentle warmth" creeps over the whole body. Morally, the diner's spirit grows more perceptive, the imagination flowers, and clever phrases fly from the lips. At the end of good meal, "body and soul both enjoy a special well-being" (p. 189). Table-pleasure is so powerful that "all human industry" has concentrated on increasing its intensity and duration, he writes. Stomachs may have had limits, but people could improve the accessories. So, they ornamented goblets and vases, ate under the open sky and in gardens and woods, invented the charms of music, and sprayed exquisite perfumes. Dancers, clowns, and other entertainers amused the eyes of diners. To all of these ancient gratifications, his recent contemporaries had contributed exquisite food, dishes so delicate that people would never get up from table if other business did not intrude.

Preferring simplicity to embellishment, Brillat-Savarin asked only four necessities—at least passable food, good wine, agreeable companions, and plenty of time (p. 191). Passing on a recipe for fondue, he recommends memorably: serve the fondue on a gently heated platter, call for the best wine, "and you will see miracles" (p. 417).

At odds with Brillat-Savarin's suggestion that the many elements of a meal generate a composite pleasure is a modern tendency to associate mood with particular foods, drinks, or diets. This view represents a somewhat "medical model" of dining rather than a convivial model, and some food scientists even speak of "functional foods," with druglike uses.

The food and drink industries implicitly market many products as improving mood. Alcoholic drink advertisements appeal to an elevated, "party" mood. The soft drink Coca-Cola is named after two traditional drugs, coca and cola, revealing its origins as an early proprietary "functional food" that still contains caffeine. Cereals manufacturer Kellogg has sold its Strawberry Pop-Tarts—pastries heated in a toaster and aimed at pre-teens—as a "mood food" by linking the snack to a social setting and a color suggestive of a particular mood (*Brandweek* [18 March 2002], p. 6). Television commercials showed girls and boys dancing, and the color red predominating, such as a red garland of lights and a girl in a red dress. The product also received placement in the television series *Gilmore Girls*, in which characters are depicted regularly eating Pop-Tarts for breakfast, suggesting that a single item can summon up a complex social setting.

Meanwhile, other researchers seek to understand why young women in particular crave and binge on sweet snacks in attempts to improve depressed moods. Many get into bulimic cycles of binge-eating and compensating, with accompanying mood swings.

Researchers led by Wesley C. Lynch found in a survey, contrary to expectations, binge eating did not lift depressed and anxious feelings but worsened them. However, moods did improve immediately before and after "compensatory activities," which included not just vomiting, but also fasting, exercise, and the use of laxatives and diuretics that did not decrease, but instead increased significantly following binge episodes and decreased immediately before and after compensatory activities" (Lynch et al., pp. 310–311). One possible interpretation of these findings is that binge eating is not the "problem" except as the prelude to self-punishing or ascetic behavior.

As the advertisers of "mood food" implicitly accept, the product does not act alone but within wider circumstances. A positive mood results most often from a satisfying meal, rich in social interactions. The aim might be to avoid solitary snacking in favor of Brillat-Savarin's nineteenth-century formula of honest viands, good company, and reduced time pressures.

**MUSTARD.** Mustard is the world's third most important spice after salt and pepper, and in temperate regions it is the most important native spice. The term "mustard" is believed to be derived from the practice of mixing the sweet must of old wine with crushed mustard seed to form a paste, *mustum ardeus* (hot must), hence mustard. The condiment is made from seeds of annual plants of the family Cruciferae, so named for the flower's four yellow petals, which form a cross. The mustard family includes the cole vegetables, radishes, turnips, cress, and horseradish, as well as many important weedy species, such as wild mustard or charlock (*Sinapis arvensis* L.).

Black mustard (*Brassica nigra* [L.] Koch), although later considered a weed, was likely the first mustard species harvested as a spice as it grew in the wild or was cocultivated with cereal crops. Its use predates recorded history with seeds, ready for sowing, found in a Bronze Age lake dwelling at the Bielersee (Lake of Bienne) in Switzerland and in vessels in northwest China dating to 5000–4000 B.C. The spice was well known to the earliest Egyptian dynasties and was spread by spice traders and conquering armies throughout Europe and Asia. The Spaniards introduced mustard to the Americas, and in California, Father Junipero Serra scattered black mustard seeds along the routes from monastery to monastery to mark the way in 1768. The bright yellow spring blooms, which mark the old trail, can be seen from the main north-south highway.

### The Mustard Species

Black mustard plants are tall (up to 3 meters) and sparsely branched, and they produce many short pods (siliques). As the pod matures, the highly pungent, small (1.5 grams per 1,000 seeds), round dark brown seeds are shed, necessitating frequent hand harvesting or cutting and stacking immature plants on the threshing floor.

The characteristic seed shedding and seed dormancy of black mustard made it unsuited to monoculture and mechanized agriculture, and the spice trade turned to the production of a closely related species, *Brassica juncea* (L.) Czern and Coss. Plants of *B. juncea*, when compared to black mustard, are shorter (1 to 2 meters) and have many upright, heavily podded branches with longer pods that retain their seeds when ripe. The seed is larger (3 grams per 1,000 seeds) but produces the same pungency. The seed color is either brown (brown mustard) or yellow (Oriental mustard).

The species originated from a natural cross between *B. nigra* and *Brassica rapa* L. (turnip rape) followed by chromosome doubling to produce a vigorous and productive interspecific hybrid. This interspecific cross is believed to have occurred more than once where the two species occupied the same region. Possible centers of origin are believed to be North Africa, northern India and Pakistan, and western China.

The third condiment mustard species, *Sinapis alba* L., is called yellow or white mustard and produces a dif-

Mustard flour and oil have strong antioxidant and antibacterial properties.

ferent pungency from both *B. nigra* and *B. juncea* seeds. From its Mediterranean center of origin, it has been widely disseminated throughout the temperate regions where day lengths (hours of sunshine) were sufficient to stimulate flowering. When moistened, the ripe seed will exude a mucilage from its yellow seed coat to form a whitish coating when dry. This may explain why white mustard is the common name in Europe, while in North America it is called yellow mustard.

Plants of yellow mustard are shorter (0.6 meters) than either *B. nigra* or *B. juncea* and have deeply lobed leaves. The short, hairy pods, with flat beaks, contain and retain 5 to 6 seeds when ripe. The seed is significantly larger than the other mustard species (6 grams per 1,000 seeds), which aids in rapid seedling establishment. In Europe the crop is frequently sown and ploughed under as a green manure crop.

### The Chemistry of Mustard

All three mustard species contain a significant amount of edible oil and high quality protein. Indeed on the Indian subcontinent *B. juncea* seeds are the second most important source of edible vegetable oil, and the residual high protein meal, after it is soaked in water, is fed to cattle. However, for the spice trade the important ingredient is the presence and concentration in the seeds of sulphur compounds called glucosinolates. Over forty such compounds are known, and their presence and quantity determines the flavor and odor of the cole vegetables as well as the taste and heat of the mustards. The glucosinolate that imparts the pungency and flavor to black and *B. juncea* mustards is called "sinigrin," while in *Sinapis alba* it is "sinalbin." When the seeds are stored whole and dry, they retain their quality for several years. However, when the cells of a mustard seed are broken and moisture is present, the enzyme myrosinase, also present in the seed, breaks down the glucosinolates to release sugar, sulphur, and the hot principles called isothiocynates. Black and *B. juncea* mustard seeds release the pungent, volatile, biting allyl isothiocynate found in powdered and Dijon mustards. Yellow mustard, on the other hand, releases the milder, nonvolatile para-hydroxybenzyl isothiocynate characteristic of hot dog or cream salad mustard.

### Making Mustard

English powdered mustard is made from brown or Oriental (yellow seeded) *B. juncea* seeds using a dry milling

In addition to the American-style hot dog mustard and the well-known Dijon style, there exists a multitude of "specialty" mustards as well as such variations as the Russian (hot and sweet), the Chinese (extra hot), the English (smooth and hot), the German (hot, smooth, and horseradishy), and the Italian *mostarda di frutla* (a thin, sweet, very hot mustard syrup containing large pieces of various fruits).

process in which the seeds are passed through a series of rollers and sieves to produce a fine flour. The seed coats, which are cracked off by the first roller, may be used in food preparation or sent to an oil extraction mill. The pure mustard flour is then blended with some yellow mustard flour, prepared separately in the same way, plus a certain amount of wheat flour to give the desired level of heat when mixed with water.

French or Dijon-style mustard is made with only brown mustard seeds using a wet milling process in which whole seeds are ground to a fine paste and the hulls or seed coats are separated with centrifuges. Some of the hulls may be added back to the paste along with vinegar, herbs, and spices. Since the hot principle allyl isothiocyanate is volatile, much of the heat is lost in the process, resulting in less pungency than might be expected from *B. juncea* seeds.

Hot dog or cream salad mustard is made from yellow mustard seeds using a wet milling process that creates a fine paste. However, the hulls are usually separated from the embryos by passing the seeds through a set of break rollers prior to grinding. The paste is then mixed with cereal flours, spices, and vinegar according to the recipe being followed.

Mustard seeds and leaves have also been harvested as a food and for medicinal purposes. The medical applications, such as mustard plasters, baths, and treatments for chilblains, are largely a thing of the past, but mustard greens and mustard seed oil are still household staples in parts of China and on the Indian subcontinent.

Four major mustard millers supply flour of various grades to processors the world over, largely replacing small local mustard millers.

## Modern Mustard

Mustard was a common spice in ancient Greek and Egyptian civilizations, where it was often eaten raw, chewed with meat to mask off flavors, to aid digestion, and for its antimicrobial properties. However, the Romans recognized mustard's potential by grinding and mixing mustard flours with unfermented grape juice, vinegar, and honey. They introduced mustard manufacture into Dijon and other regions of France and later into England. They recorded its application as a preservative and its use in sauces with meat, fish, and vegetables. In medieval times mustard making was primarily done by the monasteries, but by the thirteenth century French family firms supplied quality mustard to French royalty. In England large-scale mustard manufacture did not flourish until the sixteenth century, when large dried balls of mustard infused with horseradish were manufactured in Tewkesbury and were sold by peddlers throughout the country. Later Mrs. Clements in Durham began to mill and distribute mustard flour, a product later made famous by the competing firms of Keen's and Colman's. In the United States, R. T. French, seeking a milder mustard in the 1800s, introduced cream salad and hot dog mustard, thereby adding a new dimension to the mustard industry.

In the second half of the twentieth century, world usage of mustard more than doubled, from 75,000 tons to over 170,000 tons. Originally most countries grew their own supplies, but by the twenty-first century the predominant supplier was Canada. The United States and central Europe also are important producers. Yellow mustard has become more important with the popularity of fast-food outlets. In addition, a strong demand developed for deheated yellow mustard because of its high protein content and excellent emulsifying, water-holding, and stabilizing characteristics. It is also widely used as a meat extender in prepared meats. The hulls of yellow mustard are also in demand for the unique properties of the mucilage (vegetable gum) they contain.

Specialty mustards, which include almost every possible blend of added flavors and range of textures, have grown dramatically. Popular formulations include ingredients such as honey, beer, wines, whiskey, garlic, horseradish, lemon peel, ginger, onion, peppers, tarragon, and so forth (see Man and Weir for a more extensive list). The Mount Horeb Mustard Museum in Wisconsin boasts a collection of 3,341 different prepared mustards. The use of mustard in restaurants and in home cooking has expanded and become more subtle and more adventurous.

**MYTH AND LEGEND, FOOD IN.** Food imagery appears in the myths and legends of many cultures worldwide; for example, in the concept of the earth as a life-giving mother and as an explanation for agricultural innovation. Gifts of food were thought proper to propitiate the gods and ensure success in food production.

Across cultures, the germination of plants and their ripening and dying are identified with the cycle of human life—the regeneration of the cosmos. The juxtaposition of life with death, fertility with infertility, and order with chaos is interwoven with the ideas of salvation and revival, of which woman is a symbol and the incarnation. For example, the Aztecs believed that the earth was female and called their goddess of fertility Tlazolteotl, Mother-Earth; similarly, other examples are the Celtic goddesses Aine and Anu (Danu, Dana), the Greek Demeter, the Hindu goddess Devi, and the Aboriginal deity Gunabibi, who was called the First Mother.

Egyptian myths about eternal forces of nature center on the male deity Osiris. His death at the hand of his brother Set and his resurrection, brought about by his wife Isis and his sister Nephtida, is associated with the cycle of plant vegetation and with the cereals that are sown after the harvest and regenerate with the coming of spring. The snake goddess Renenutet has custody over the harvest and field crops.

In ancient mythologies, everything is a gift of the gods' generosity, even the knowledge needed to improve food production. Examples appear cross-culturally: the Sumerian god Enlil makes a hoe and gives it to man so that he can cultivate land; the Chinese are taught how to cultivate land by the Divine Farmer, Shen-nung, who is the first to plow and sow grain, which rained from the sky or was dropped by the Purple Bird. A Hindu who sincerely worships goddess Devi is rewarded with rice by the household goddess, Annapurna; Indian bees make honey because of the divine intervention of the twin brothers Avins; and the Greek goddess Athena creates the olive tree from the depths of Attica's barren earth. The short poem in honor of Ninkasi, the Mesopotamian goddess of strong liquors, relates that it is due to her grace the dough rises when beer leaven is added to it, and that it is she who inspires bakers add sesame seed and herbs to bread.

In the epic of Gilgamesh, the goddess Ishtar asks her father, the god Anu, to use the heavenly bull to punish Gilgamesh. When Anu replies that the bull would not leave a single wheat grain on the earth for people, the

Many foods play a significant role in old myths and legends, such as the pomegranate in the Greek myth of Persephone. Other foods are themselves the subject of complex mythologies, and one of these is the pretzel. The commonly told story (at least in America) of the invention of the pretzel by an Italian priest to signify crossed arms in the act of blessing was created in the early 1900s to dilute the association of pretzels with beer drinking during Prohibition. In fact, the twisted pretzel traces to pre-Christian cult foods in the Rhine Valley, although its name derives from *bracellus* (an arm band or bracelet). The pretzels shown here were displayed in the Alsatian town of Wissembourg, France, during Christmas 1998. © DAVE BARTRUFF/CORBIS.

goddess assures him that the grain reserves stored in the granaries of Uruk were sufficient to last for seven successive years of crop failure, and that they could sustain both people and cattle.

The association between humans and the gods endows food with a sacred quality, a mystical solidarity of man with plants and animals. When humans consume votive food they are in a way convinced that ultimately they consume a divine being. Offering food is a common practice in mythologies, and in order to prevent the wrath of the gods, priests were obliged to procure food for the sanctuaries.

## TEA AND COFFEE IN MYTHOLOGY

In Chinese and Japanese cultures, tea is a frequent subject matter of legends. The tea plant was created from eyelids of a certain Buddhist monk, or sage, who, wanting to punish himself for falling asleep during meditation, cuts them off and discards them with contempt. Each eyelid gives rise to one tea shrub. According to the Japanese version of this legend, the eyelids belong to Bodhidharma (Daruma), who cuts them off as a preventive measure, since he wants to be unable to ever close his eyes.

The discovery of coffee is sometimes ascribed to goats. Coptic monks, who are compelled to observe a strict religious order of overnight prayers, notice that goats that had nibbled the leaves and fruit of wild coffee shrubs became excited and could not sleep at night. Thus, the monks follow the goats and, although they do not really like the taste of the leaves and bean, they are greatly satisfied with their unusual effect. Another, more poetic legend has Arabic origins: the first cup of this beverage was served to Muhammad by the Archangel Gabriel. The drink has an amazing effect. Right away Muhammad mounts his stallion, defeats forty knights in tournament, and lets forty Arabic ladies "taste the sweetness of love."

Each deity has a liking for a particular food; for example, lettuce is the favorite vegetable of the Egyptian god Set. In Hindu mythology, the god Dharmathakur accepts only white offerings (rice, milk, poultry), while the demonic and semi-divine female Dakini acquires strength from raw meat. As a child, Krishna goes into peasants' houses and pinches butter from them as he is very fond of it. The Hindu made offerings of boiled rice mixed with sesame seed, milk, ghee, and honey to their mystical ancestors residing in the other world.

Before any undertaking, a Greek promised the gods he would make some offering to them in order to gain their support. If someone could not afford to buy a sacrificial animal, he made a cake baked in the shape of an ox, a cow, or a sheep. Replacement offerings were made to gods when cities were besieged by enemies, or when meat was in short supply.

Beer is a food product most frequently referred to in mythologies of Mesopotamia, Egypt, and Scandinavia.

Mesopotamian mythology in particular abounds in episodes with beer in the background. The goddess Inana makes the god Enki drunk with beer in order to steal the heavenly secrets away from him. In turn, in Greek mythology wine plays the most prominent role. On a holiday celebrated in December, when the new wine was stowed in granaries, the Greeks would kill a goat and sprinkle vine roots with its blood. Liquors were even thought to make the horrid existence in the underworld more pleasant; for example, in the Welsh underworld, in Annwn, there is a spring from which wine was flowing.

After his exhausting journey in search of the "herb of life" Gilgamesh falls into a deep sleep that lasts seven days. The host of that place, Ut-napishtim, says to his wife: "Start [to] bake bread and every day put one loaf next to his head and make a sign on wall so that you know how many times you have baked." The ritual meal in praise of Aboriginal deity Djanggalwul was composed exclusively of fresh bread made of sago nut flour. Eating it formed a sacred bond of friendship between the participants of the feast.

In Greek mythology, ambrosia is the food that gives the Olympian gods eternal youth and beauty. Unlike nectar, which is a drink, ambrosia is probably a dish. It was believed to make even an ordinary person immortal. The Indian counterparts of ambrosia are *amryta*, the nectar found at the ocean bottom, and *soma*, a heavenly elixir that ensures immortality on earth. The Australian Aborigines told tales about an elixir of immortality, though this elixir had no name.

**NAMING OF FOOD.** Foods are named primarily according to their origins. Foods from the plant kingdom usually have the same name as the plant, such as *carrot*, *potato*, *peas*, and *spinach*. Sometimes the name of the food is from the fruit (the seed-bearing part of the plant), such as *apple*, from apple trees, and *raspberry* from raspberry bushes.

Food from animals usually has the same name as the animal: *lamb*, *chicken*, *rabbit*, *quail*, *salmon*, *Dungeness crab*, *snails*. The exceptions are words such as *calf* and *veal* or *pig* and *pork* or *sheep* and *mutton*, where the former word is of Anglo Saxon origin and the latter of French origin. A few remnants of Anglo-Saxon names remain, as in *ox-tail soup* or *pigs' feet*. The names of animal parts when cooked and eaten often refer to the common anatomical names, such as *wing*, *breast*, or *leg* of birds and *rib* and *tongue* of mammals. However, most cuts of meat have their own special names: *sirloin*, *strip steak*, *lamb chop*. *Bacon* and *ham* denote that the meat is from a pig and that it is smoked. Innards like liver and kidneys are the same as the organ name. However, some interior parts have better-sounding food names, such as *sweetbreads* for *pancreas*, *tripe* for the *stomach* of a ruminant, *roe* or *caviar* for *fish eggs*, and *mountain oysters* for *testicles*.

### Names of Dishes

Names for prepared foods follow several patterns. The commonest is a phrase with the main ingredients: *chicken almond*, *beef and mushrooms*, *creamed tuna casserole*, or with the cooking method as well as the food: *poached eggs on toast*, *pork and vegetable stir-fry*.

Another common pattern is to name foods after places. The meaning only indicates an origin and/or style. Sometimes the meaning is transparent, as in *Polish sausage*, *Belgian waffle*, or *Spanish omelet*, but often additional knowledge is required. *Florentine* (named for Florence, Italy) is for dishes with spinach, *Bolognese* (from Bologna) is with a meat sauce, and *Bologna* is a sausage. *Veal Milanese* (Milan) or *Wiener Schnitzel* (Vienna) is breaded and fried veal cutlet. *Provençal* (Provence) means made with tomato, garlic and olive oil, and *chicken Kiev* is chicken breast wrapped around butter, breaded, and fried, *Salad Niçoise* (Nice), *Mongolian hot pot*, *Peking duck*, *Buffalo wings*, and *baked Alaska* are other examples.

*Chicken Marengo* was named in honor of Napoleon's victory at Marengo. Occasionally the name is misleading. French toast is an American dish, while *homard à l'américain* 'lobster American style' is a French dish. French-fried potatoes are common in France under the name *pommes frites* 'fried potatoes'.

A small number of words derived from place names have been resegmented and reanalyzed. Hamburger and Frankfurter were named after the German cities of Hamburg and Frankfurt, and Wiener is from Wien, the German name for Vienna. Hamburger was resegmented as ham + burger, although the food is made with chopped beef. Burger became a combining form to be added to any food served with ground beef (*cheeseburger*, *baconburger*) or some meat instead of beef (*chickenburger*, *fishburger*), or for a particular style (*California burger*). Vegetarian versions are *veggie burgers* or *garden burgers*. Subsequently, *burger* has become an independent word. *Frankfurter*, often shortened to *frank*, has also become a combining form, yielding new words like *turkeyfurter* or *turkeyfrank*, with each part of the word combining with new parts. *Hot dog*, an informal term for frankfurters, has generated *Tofu Pup*, a vegetarian sausage. It also illustrates the trendiness of wordplay.

Some dishes are named after people, either for the inventor or in honor of some famous person. *Sandwiches* were invented by the Earl of Sandwich, and *Beef Wellington* honors the Duke of Wellington. *Beef Stroganoff* is a French dish created to honor the Russian diplomat Stroganov. Other examples are *Oysters Rockefeller*, *Pavlova*, a meringue dessert created to honor the dancer Anna Pavlova, and the pastries named for Napoleon and Bismarck.

French has had an especially strong influence on English names for food and dishes. The phrase *à la* appears in several dishes. One phrase taken from French is *à la reine* 'to the queen' or 'in honor of the queen' for creamed foods often served on a puffed pastry. This has led to *à la king*, a mixture of French and English that violates French grammar, since "la" is the feminine definite article, and king by virtue of its meaning would be masculine (if English still had grammatical gender in its definite articles). Other examples are *riz à l'impératrice* 'rice pudding' literally 'to the empress' and *à la mode* 'with ice cream' (literally 'in the style').

English speakers have borrowed freely from other languages for hundreds of years, taking the original spelling (if that language uses Roman letters) as well as an anglicized pronunciation. (This phenomenon is part of the reason for the irregular spelling of English.) Food names have been heavily borrowed along with the dish: *sauerkraut* and *strudel* (German); *soufflé*, *mousse*, *crêpes*, *meringue*, and *fondue* (French); *spaghetti* and other pasta names as well as *pizza* and *spumoni* (Italian); *souvlaki* (Greek); *goulash* (Hungarian); *tortilla* (Spanish); *paella* (Catalan); *guacamole* (Nahuatl, a native Mexican language); *blini* (Russian); *cole slaw* (Dutch); *curry* (Tamil, a language of South India); *chutney* (Hindi); *shish kabob* and *baklava* (Turkish); *couscous* (Arabic); *sushi* and *tempura* (Japanese); *won ton* (Chinese); *succotash* (Narragansett, a North American Indian language); and *matzoh* (Hebrew).

### Marketing Strategies

In selling foods, whether in stores or restaurants, attractive names are selected for the product or the dish. Often foreign-language equivalents are used, sometimes along with the English equivalent. For example, spaghetti in tomato sauce might be labeled pasta in marinara sauce. In addition to the euphemisms for innards described above, the names of pet foods are especially interesting since the names are intended to appeal to the owners. One popular brand of cat food has names like “country-style dinner,” “mariner’s catch,” and “prime entree.” The ingredients listed in small print on the label do not sound so nice.

Zwicky and Zwicky (1980) in their investigation of menus in American restaurants show that names both inform and advertise. Two examples they present are “Entrecôte au Poivre Madagascar—sirloin steak topped with green peppercorns, served with cream sauce and cognac” (Zwicky and Zwicky, p. 86) and “sautéed shrimp in garlic butter—the zesty garlic butter brings out the best in this epicurean treat from the sea” (Zwicky and Zwicky, p. 87). The first example describes and the second advertises. Zwicky and Zwicky observe that French is used on menus frequently because of the traditional association of French with fine food. The restaurant need not be French, and the French is often ungrammatical or mixed with English. Therefore, one finds *Cuisine de Holland* and *Stuffed Tomato aux Herbs, Shoreham Style* (Zwicky and Zwicky, pp. 89–90).

Since many people are on diets for reason of health and/or weight control, there is concern with calories and with fat. The food industry has responded by offering products with less fat and fewer calories. One word for referring to these products is “light,” sometimes spelled “lite.” The Miller Brewing Company used the word to denote a beer with fewer calories than regular beer. Since a light beer is ambiguous—it can be light in color (pale vs. amber or dark)—the spelling difference can disambiguate the two senses. Although other beer companies have been prevented from using this spelling, lite has

spread to many other foods with fewer calories than the normal counterpart. More recently, “free,” a clipping of “fat free,” has emerged to denote foods without fat.

**NATIONAL CUISINES, IDEA OF.** Cuisines and nations are artifacts of human enterprise, will, and imagination. They refer ostensibly to material things: to the earth, to the natural world, to particular geographical locales and the products of these places. In this sense, cuisines tell one something about food, and nations tell one something about places. Cuisines, too, are made up of earthly products, such as butter, beef, saffron, and garlic, much as nations inhabit physical localities, whether protruding landmasses, landlocked mountains, or chains of islands. In the modern period, however, foods have become associated with cuisines and places with nations to such an extent that one does not perceive any difference between them. National cuisines are a product of the modern emphasis on nationalism and the nation-state.

In fact, the coining of “national cuisines” has become an almost exclusive means of organizing the link between food and place. One talks with ease of Germany and German cuisine and India and Indian cuisine, as if German cuisine and Indian cuisine have existed as long as the mountains, valleys, and lakes that define their namesakes’ topographies. If the history of the subcontinent, and the food practices of people there, are reviewed, the limits of the term “Indian cuisine” will be fast apparent. The food habits of the Punjabi Sikh and the Kerala Christian, for instance, have little in common, though both groups occupy India and eat its food products. While a handy moniker to grasp onto the food habits of a group of people, “Indian cuisine” is not a product of nature. Classifying a cuisine helps mark a geographical locale as a nation; it allows people to imagine national unity and to create convenient categories for understanding food practices. The convenient shorthand of “German cuisine” and “Indian cuisine” belies the complex historical formation of national cuisines, and their link to nationalism, a way of speaking about place, identity, and sovereignty.

Because of the tangible and visceral nature of food, nationalists have long used food to help solidify claims and gain legitimacy. This can clearly be seen in the shift from food to cuisine as a way to mark ownership over ingredients and practices understood to come from a certain place. For at least two hundred years, France has been a geographical region where arguments have been made for the authenticity of national cuisines by citizens, the state, and culinary professionals. The arguments concern the natural, authentic nature of “French cuisine” as a national cuisine. The French also often argue for the superiority of French cuisine in general. A historical examination of cookbooks from this region reveals a shift in the assumptions about audience and organization away from noble patrons toward fellow citizens. This shift occurred from the sixteenth century to the early part of the nineteenth century. By the 1880s, almost all cookbooks were aimed toward national citizens.

More recently, newer nation-states such as Mexico and Israel have promoted their national cuisines as a means of legitimizing their claims to nationhood. But, according to anthropologist Sidney Mintz, “a national cuisine is a contradiction in terms. . . . for the most part, a national cuisine is simply a holistic artifice based on the foods of the people who live inside some political system, such as France or Spain” (Mintz, p. 104) Yet this “holistic artifice” has become a very successful enterprise. All manner of food ways, now packaged as “national cuisines,” are promoted in restaurants, cookbooks, tourist guides, and television shows. In particular, cookbooks have been very effective at creating and promoting such assumptions; contemporary cookbooks include such titles as *A Taste of India*, *Mastering the Art of French Cooking*, and *The Art of Mexican Cooking*. The discourse of food writing has largely become bounded by the notion of national cuisines: National cuisines are seen as natural occurrences and the culinary discourse reflects that very assumption.

To really comprehend the tremendous complexity and diversity of human food practices, it is necessary to move beyond the discourse of national cuisines. Food—the raw ingredients, the cooking techniques, the ritual practices, the social significance—is ultimately more fluid, varied, meaningful, and powerful than the reliance on national cuisine as a category of explanation allows for in exploring it. Perhaps the twenty-first century, if significant in demonstrating the limited control of any sovereign nation-state, will be the period when food is removed from the nationalist agenda.

**NATIVE AMERICANS.** See **American Indians.**

**NATURAL FOODS.** The concept of natural foods is obscure from many perspectives. Although international literature offers no clear definition, the term is used in food surveys, in the food industry, in the marketing of foods, and in modern discourses surrounding food choice. “Natural” is defined as ‘produced by nature, that is, not produced artificially’ in *Funk and Wagnalls Standard Dictionary*. Since all food can be said to be produced by nature, the term “natural foods” becomes even more unclear unless one considers the meaning Felipe Fernández-Armesto has proposed: “the oyster is eaten uncooked and unkilld. It is the nearest thing we have to ‘natural’ food—the only dish which deserves to be called ‘au naturel’ without irony” (p. 2).

If the concept of natural foods originates from the French phrase *au naturel*, that is, eating something uncooked and alive, it would relate first to modes of processing. An “unkilled” food like the oyster is a food uncooked and is, by that definition, a food that has not been altered by human hand. Thus natural foods are foods not deliberately altered in the course of production and processing. Asked in a study how they perceived naturalness in relation to food production, respondents in England and Denmark said they perceived organic food and free-range livestock products as the most natural foods and genetically modified foods as the most unnatural foods (Von Alvensleben).

Furthermore, natural foods can be interpreted in terms of connections to nostalgic rural life (Lupton). Yet regional foods, products that are not imported from exotic, faraway lands and not distributed in ways injurious to the environment are also representations of natural foods. Moreover, the concept of natural foods is related more to some groups in society than to others. Some associate natural foods with specific food choice ideologies, such as vegetarianism, and thus exclude certain animal products while including plants, cereals, fruits, and berries, preferably produced in an organic or ecological way (Lindeman and Sirelius).

The marketing strategies for natural foods may be understood on two levels. First: natural foods are considered unprocessed foods in the sense that they are not influenced by industry for mass production. Second: natural

foods are seen as originating in the vegetable kingdom. Both dimensions are marketed as healthy for people and the environment.

### **Contradictions in Health and Purity**

The marketing of natural foods actually refers to health issues. Natural foods are projected as guaranteeing a long, healthy life since they are portrayed as foods that can prevent diseases and aging. In this concept lies the belief that natural foods are pure and free from harmful and unwholesome components. Pure food is perceived as natural, simple, unspoiled, and earthy, but at the same time it is expected to be germ-free, biologically cleansed, and scientifically aseptic (Mintz).

Natural foods in fact can include more harmful and naturally occurring toxic substances than highly processed food. The latter, thanks to modern developments in biotechnology, (i.e., genetic manipulation) can be more “healthy” and can more effectively prevent diseases than the so-called natural foods (Coveney and Santich). Advances in biotechnology have produced foods that are much safer from a hygienic perspective with the same tastes, appearances, textures, and colors as foods produced in the conventional way. This is the ultimate goal for the modern food industry, and these are the foods modern consumers actually demand and look for even though they are not always aware of it.

### **Quality Aspects of Natural Food**

The concept of natural foods is closely related to quality aspects of food. Adulteration of food has been evident since the growth of towns and the development of food distribution in medieval Europe. Adulteration became more prevalent in the late nineteenth century, a period also characterized by the food scientists’ obsession with purity (Tannahill). This obsession was mainly a reaction to the development of the food industry and the loss of control over local food production, but it can also be linked to the development of food science per se. New scientific methods enabled scientists to measure and detect impurities in food. Thus the quality aspects of food were seen under the microscope, that is, scientists could actually see with their own eyes the bacteria, microorganisms, and chemical residues in the food; therefore, food was determined chemically clean or not. However, as Sidney W. Mintz emphasizes, this state is not the same as a natural one. Nature is not chemically clean.

At the same time a new genre of books with advice and guidelines on how to shop for safe, unaltered foods was published widely in Europe. The consumers, mostly women, were told what foods they should be suspicious of, what foods to avoid, how to detect adulterations in food, and so on. In these books and in the general debate in the newspapers, the development of food industries and fast-growing global trade was much criticized. Foods produced in the consumer’s own country and sold by local, well-known salespeople were recommended

(Fjellström). The debate continued in the twenty-first century within the European Union (EU) despite the fact that most states in the EU have effective measures to control quality in food production and distribution. Consumers in Europe and the United States fear unnatural foods produced outside national and regional borders.

### **The Ideology about Nature and Food**

The vision of the foods eaten by humankind in prehistory is one of natural and healthy foods from a nutritional point of view (Jenkins et al.). This diet is perceived as plant-based; high in vegetable protein, dietary fiber, and antioxidants; and low in saturated fat. It is considered the best alternative for modern people forced to eat the food of the supermarket, which is characterized as bottled, canned, refined, preserved, and frozen.

The ideology and attitudes toward the wild and natural landscape on the one hand and the domesticated and cultivated landscape on the other shifted back and forth throughout the first millennium B.C.E. (Montanari). For example, in Greek and the Roman cultures the untilled, uncultivated landscape or nature was seen as something negative, the opposite of the civilized and human world. Only unfortunate people obtained food in wild nature. Although the vegetarian diet, as opposed to the animal one, appealed more to both the Greeks and the Romans, it had to derive from land cultivated by people. During the seventh and eighth centuries C.E. in Europe the preference for nature and for the wild landscape as a source of a daily food supply became more dominant among the lay nobility, while domestically produced foods were preferred by groups within the church and in monasteries. In the early part of the second millennium C.E., the dominant ideas supported an effective medieval agricultural system. Foods obtained from the wild or naturally grown were regarded as unsuitable for human consumption (Montanari).

In eighteenth-century Scotland the physician George Cheney won a reputation for his ideas on health and illness. Natural foods were once again in favor. Cheney saw natural foods as those that remained unaltered by strange preparation techniques and ingredients, although he was not a vegetarian (Beardsworth and Keil). The development of organicism in mid-twentieth-century England preceded the ideology of natural foods (Matless). Important symbols within this movement were the earth and the soil. Values such as nature and wholeness were seen as the right kind of values for the survival of humankind, just as production methods and geographies of foods were emphasized as important for people’s health. Organicists were critical of the global food production and distribution industries, thus their approach can be understood as a critique of modernity.

### **Natural Foods and a Critique of Modernity**

The choice of natural foods could be interpreted in terms of Anthony Giddens’s theories about people’s calcula-

tions of risk elements in modern everyday life. Health issues, fear of diseases, and ultimately existential questions, such as the fear of death, are the underlying reasons that people began to examine what foods they could trust in a global society, where multinational food industries control food production and distribution and where experts have commandeered the knowledge of what is safe and healthy food. In his well-known culinary triangle Claude Lévi-Strauss emphasized that raw food was related to nature, while cooked food handled in vessels made by people had become culture. At the beginning of the twenty-first century the discourses surrounding food, especially so-called natural foods, involve new and different meanings and symbols. In some groups, particularly those who favor natural foods, nature and rural living are favored before culture and urban living (Lupton). Thus Lévi-Strauss's ideas about the raw and cooked have changed place. Raw food rather than processed and cooked food is considered culture among some groups.

**NIACIN DEFICIENCY (PELLAGRA).** Deficiency of the vitamin niacin can result in the disease pellagra. This illness is characterized by the appearance of severe dermatitis on the parts of the skin that have been exposed to the sun, with deep cracking and flaking. Sufferers also have diarrhea and, in many cases, some kind of dementia. The condition typically flares up during spring, as sunshine becomes stronger. In practice, patients were often found to be deficient in the vitamin riboflavin in addition to niacin. Both in the Old and New Worlds, the condition has almost always been confined to people consuming corn (that is, maize) as their staple grain. The explanation is complex. We can synthesize niacin for ourselves to some extent if our diet contains a good supply of the amino acid tryptophan because we have enzymes that can, in a series of steps, turn a portion of any excess tryptophan molecules into niacin. The problem with corn is that the proteins that it contains have an unusually low proportion of tryptophan, and this is insufficient to provide a second source of the vitamin. Mature corn, like the mature grains of other cereals, does contain niacin, but it is mostly present in linkage with other compounds that make it essentially indigestible, because the digestive enzymes in the gut cannot break these linkages. In Central America and Mexico, where corn has been the staple grain for millennia, the populations have learned to soften the grains by soaking them with lime (calcium hydroxide) before grinding them to a paste. It is now realized that, in addition to its softening action, the alkaline lime liberates the niacin from its linkages, so that it is now nutritionally available. This is, at least, a partial explanation for the freedom of these peoples from pellagra. In addition, if a diet rich in maize is supplemented with a diet that also uses beans as a staple, as is the case among the traditional natives of Mexico, then the low level of tryptophan in maize is compensated by the higher tryptophan level in beans. Many types of long-established diets have this type of essential amino acid complementarity among the foods consumed.

However, when corn was brought back to the Old World, and gradually came to be adopted as a staple food in Southern Europe, but without the use of lime in its preparation, pellagra became a serious problem. In the nineteenth century it was suspected that corn developed toxic molds during storage. In France its use as a food crop was made illegal, and in Italy a special class of “pellagra hospitals” was established. In the southern regions of the United States, pellagra became a serious problem from about 1910 onward. There had been no obvious change in dietary habits to explain this, but it is now realized that corn processors had introduced a new method of milling corn that separated the germ. This was advantageous in reducing the oil content of the cornmeal and increasing its storage life, but it further halved the tryptophan content of the meal. The average consumer in the South was using approximately equal parts of cornmeal and of white wheat flour that was somewhat richer in tryptophan. It appears that the change in milling was just enough to tip the balance toward the appearance of pellagra in those with only low intakes of good supplementary foods such as meat and milk. Niacin is now one of the synthetic vitamins included in the supplements routinely used to enrich flours in many Western countries.

**NOODLE IN ASIA, THE.** Noodles originated in northern China during the last half of the Han Dynasty (206 B.C.E.–220 C.E.) when large-scale wheat grinding became available, providing flour to make *mian*, *mein*, or *mi*, the Chinese word for noodle. We learn about the earliest noodles from Shu Hsi, one of China’s most learned men, who in 300 B.C.E. wrote a *fu* or rhapsody on noodles, in which he provided detailed recordings of noodle making. For centuries, *la mian* or hand-pulled or hand-swung noodles were popular. The chef grasped a length of dough between two hands, stretched it with a toss of several feet, and repeated the tossing and extending until the dough divided into thinner and thinner strands, resulting in soft, smooth, and chewy noodles.

In the centuries that followed, variations of noodle making were introduced. In the Tang Dynasty (618–907 C.E.), noodles were first cut into strips. Then, in the Yuan Dynasty (1271–1368 C.E.) the making of dried noodles began (Ang, p. 46).

Noodle maker in Turpan, Xinjiang, China. PHOTO BY GLENN MACK.

With travel and trade, noodles migrated into the rest of Asia. Noodles moved from China to Japan to Korea and to Southeast Asia. The Chinese influence is first evident in the name for noodle. The Chinese word for noodle, *mian* or *mien* or *mi* became *men* or *menrui* in Japan, *myun* in Korea, and *mee* in Thailand. It was even believed that Chinese noodles moved into Europe. According to legend, Marco Polo discovered pasta in China and took the idea home. But it was misinterpretation of his records that started this story because pasta was known to the ancient Greeks and Romans—a culinary evolution independent of China.

Asian noodles are distinctive because of the assortment of flours used. The notion that rice is the dietary staple in China is misleading as the majority of China eats wheat products. Southern China with its monsoon rains provides perfect rice-cultivating conditions while the large area north of the Yangtze River is excellent for wheat. Northern China, Korea, and Japan use wheat flour. Buckwheat noodles are found in Japan and Korea. Southern China uses wheat flour with the addition of egg as well as rice flour. Southeast Asia uses mostly rice flour, but also mung bean flour. Other Asian noodles are made

from potato starch, sweet potato, soy bean, yam, and dried shrimp. They come dried, fresh, thin, thick, coarse, flat, round, and in broken sheets. Each country has similar yet distinctive ways of making noodles.

## China

In China, the most popular noodle is the regular *gan mian* or *mian*, made of wheat flour and water. Salt is sometimes added, and cornstarch is sprinkled on fresh noodles to keep them from sticking together. Dried wheat noodles are either 12-inch lengths or, in the case of thinner noodles, nest-like swirls. Egg noodles or *dan mian*, occasionally flavored with shrimp and yellowish in color, are popular in southern China. *Chow mian*, or stir-fried noodles, is perhaps the most popular noodle dish.

Other noodles eaten in China are made with rice flour or mung bean flour. Dried rice noodles, *mi fen*, or rice sticks or rice vermicelli come in different widths, but in China, the thin, white opaque white noodles are most popular; they are softened in hot water or immediately puffed up when tossed in hot oil. *Sha He fen* or rice noodles from the southern village of Sha He, or vermicelli sheets, are wide, slippery, rice noodles sold in large squares. These fresh noodles made from rice flour, cornstarch, and potato starch are used in soups and stir-fried in a dish called *chow fen*. At other times, the sheets are filled with beef or shrimp and then rolled and steamed. Mung bean noodles or *fen si* (literally translated ‘powdered silk’) or cellophane noodles, bean threads, glass noodles, or vermicelli are from the starch of mung beans. They rehydrate in hot water to a slippery, translucent noodle, or puff up when fried in hot oil.

## Japan and Korea

Japan is the most noodle- or *menrui*-consuming nation on earth. Japanese noodles include wheat-based noodles found in Osaka or southern Japan, and buckwheat-based noodles associated with old Edo, now Tokyo, and the north country. Wheat noodles include *udon*, which are thick round, square, or flat noodles; *kishimen*, which are also wide and flat; *biyamugi*, which are round, very slender and served cold; *somen*, which are even more slender and slightly moistened with cottonseed or sesame oil, and also made with tea powder, *cha somen*; egg yolk, *tomago somen*; or tinted with red perilla oil, *ume somen*. Buckwheat-based noodles, or *soba*, are mixed with wheat flour. These noodles are long, thin, and gray-brown in color. A variation of this noodle, made with green tea, is *cha soba*.

*Ramen*, the most popular noodle in Japan, is of Chinese origin. These noodles are steamed and dried, making them easily rehydrated for quick eating. *Harusame* or ‘spring rain’ or cellophane noodles are made from Japanese potato starch or Chinese style from mung beans. Finally, *shirataki* or ‘white waterfall’ is made from the starch of the devil’s tongue or *Amorphophalus konjac*.

TABLE 1

Asian Noodles		
Name	Ingredients	Use
<b>Chinese Noodles</b>		
wheat noodles (mian, gan mian, mien, mi)	wheat flour and water	stir-fries, soups
egg noodles (dan mian)	wheat flour, egg, and water	stir-fries, soups
mung bean noodles (cellophane noodles, bean threads, glass noodles, fen si)	mung bean starch and water deep-fried	stir-fries, soups,
rice noodles (rice sticks, rice vermicelli, mi fen)	rice flour and water	stir-fries, soups, deep-fried
vermicelli sheets (Sha He fen)	rice flour, cornstarch, potato starch, and water	soups, stir-fries
<b>Japanese Noodles</b>		
ramen noodles	wheat flour, egg, and water	soups, stews, stir-fries
devil’s tongue starch noodles (shirataki)	devil’s tongue starch or Amorphophalus konjac starch with milk of lime	soups
soba noodles	buckwheat flour, wheat flour, and water	soups, stews, salads
somen noodles	wheat flour and water	soups, salads
udon noodles	wheat flour and water	soups, stews, salads
<b>Korean Noodles</b>		
buckwheat noodles (naeng myon)	buckwheat flour, wheat flour, and water	salads, soups
sweet potato noodles (vermicelli, tang myon)	sweet potato flour and cornstarch and water	salads, stir-fries
<b>Thai Noodles</b>		
thin rice noodles (rice sticks, rice vermicelli, sen mee)	rice flour and water	soups, stir-fries, salad
flat rice noodles (flat rice sticks, rice vermicelli, dried gway tio, banh pho)	rice flour and water	soups, stir-fries, salad
vermicelli sheets (Sha He fen, gway tio)	rice flour, cornstarch, potato starch, and water	soups, stir-fries
mung bean noodles (cellophane noodles, bean threads, glass noodles, woon sen)	mung bean starch and water	soups, stir-fries, salads
<b>Vietnamese Noodles</b>		
thin rice noodles fillings (rice sticks, rice vermicelli, bun)	rice flour and water	salads, soups,
flat rice noodles (flat rice sticks, rice vermicelli, banh pho)	rice flour and water	soups, stir-fries
mung bean noodles (cellophane noodles, bean threads, glass noodles, bun tau)	mung bean starch and water	salads, soups, fillings

*Udon* is usually served in broth with chopped scallops or *shichimi* or a seven-spice mixture consisting of red pepper, *sansho* or Japanese prickly ash pepper pods,

dried mandarin orange peel, black hemp seeds, dark green nori seaweed bits, and white sesame seeds. *Soba* is traditionally served on bamboo slats inside a square wooden box with a dipping sauce made of *dashi* or a bonito flake-*kombu* seaweed broth. If the noodles are presented cold, then the dipping sauce may be accompanied by sliced scallions, wasabi or Japanese horseradish, and grated daikon or Japanese white turnip. *Somen* is usually served cold. *Shirataki* comes packed in lime water and needs to be parboiled before using in *sukiyaki*, a popular beef dish made in a shallow cast-iron pan.

Korea's proximity to Japan and China is reflected in the noodles eaten there. Koreans enjoy buckwheat noodles or *naeng myon* cold, much as the Japanese do, but with some unique variations. The Korean version of the Chinese mung bean noodle is *tang myon*, which is made with sweet potato and cornstarch. These grayish, rubbery noodles are used in stir-fries.

### Southeast Asia

Vietnamese noodles come in various sizes and are prepared in different ways. *Bun* or rice vermicelli comes in small and thin sizes, and in much wider widths. Small or thin noodles are used in salads, *bun bo*, while the much wider noodles are found in soups. *Banh pho* is a flat rice noodle that looks like linguine and comes in widths of small, medium, and large, and is used in soups and stir-fries. Vietnam's most popular soup is *pho bac*, or rice noodles in beef soup served with slices of beef and fresh herbs. *Mi soi*, thin egg noodles, is of Chinese origin. *Bun tau* or mung bean noodles, cellophane noodles, bean threads, or glass noodles are made from mung bean starch. After these thin, wiry white sticks are softened in hot water, they are used in soups, stir-fries, and fillings.

In Thailand, noodles also come in every size and shape, from flat white rice noodles or *gway tio*, to brittle white rice stick noodles or *sen mee*, to glass-like bean thread noodles or *woon sen*. *Gway tio* can be served in stir-fries or soups. *Sen mee* is served fried, stir-fried, or in soups. *Woon sen* is used in soups and stuffings for its slippery texture. Popular dishes in Thailand are the *pad thai* noodle, which uses thicker-width rice noodles, and *mee krob*, which uses a thin rice vermicelli that is fried.

In other parts of Southeast Asia, variations of the noodles found in China, Vietnam, and Thailand are eaten. In Malaysia, rice vermicelli noodles are combined with a tamarind mackerel sauce for *laksa asam*. In the Philippines, rice vermicelli is stir-fried with meats and vegetables to make *pancit*. In Singapore, *char kway teow* or flat white rice noodles are stir-fried with seafood, while egg noodles or *Hokkien*, yellow noodles, and rice vermicelli are stir-fried in the same dish with meat, seafood, and vegetables for *Hokkien mee*. Though there may be similarities in preparation of the noodle dishes, the flavors are distinctive of each region because of the indigenous ingredients used.

### Ceremony and Symbolism

Noodles not only play an important role in Asian daily eating, but contribute to rituals in honoring the dead, celebrating birthdays of the living, and marking other special occasions. They are brought to the grave of a deceased family member or friend on the twenty-fourth day after the first of each lunar month. It was Emperor Chu Yuan-Chang of the Ming Dynasty (1368–1644) who built a *t'ai miao* or shrine to the imperial ancestors where he placed spiritual tablets of his paternal relatives for four generations. Offerings of foods, including noodles with sesame oil, were brought to the shrine on the appropriate day.

After the birth of a child, especially a son, the mother's family sends over gifts for the new mother of wheat flour or wheat flour noodles, chickens, and a basket of eggs. For the birthday celebrant, a plate of long thin noodles expresses a wish of long life. Long-life and happiness wishes with noodles continue with the New Year feast.

In Japan, *soba* is usually the final item eaten on New Year's Eve. This dish is called *toshi-koshi* which means 'year-passing' and symbolizes the old year passing. It is customary for a person who moves into a new neighborhood to make gifts of *soba* to households next to and in front of one's new house. The word for *soba* is a homonym of the word *soba* meaning 'near' or 'next to'.

### Summary

One cannot think of Asia without thinking of noodles. Noodles, the symbol for longevity, play important roles in everyday eating as well as for special occasions and celebrations. Consumed at home or on the streets, noodles originated in China but are a permanent presence in all of Asia.

## NOODLE IN NORTHERN EUROPE, THE.

The word “noodle” is German in origin. By the mid-1400s, it appeared as *Nudel* in connection with *composita*, layered dishes employing cabbage, dried fruits, some form of meat (usually ham), and dumplings. There is no firm agreement among German food historians about the origin of the term *Nudel* even though it can be found in German- and Yiddish-speaking communities in Middle Europe by the 1500s. For example, in the 1581 cookbook of Hungarian-born Marcus Rumpolt, there is a recipe for *Nudeln aus der Grafschaft Tyrol* (Noodles from the county of Tyrol), evidence of the fact that, by the 1580s, there were already many regional variations in methods of preparation and serving contexts. Furthermore, the plural form of the word passed into French as *nouilles*, probably via Alsace. The original meaning, however, was *Teigwerk*, anything made of dough regardless of shape. Even to this day, the *Nudel* falls under the broad category of *Teigwerk* in most German-language cookbooks. The distinguishing difference between *Teigwerk* for pie crusts and doughs for noodles is that the latter are boiled or in some manner cooked with steam or water.

The most commonly accepted explanation for the origin of *Nudel* is that it derives from *Knödel*, or, as the word appeared in a number of old German dialects, *Nutel*, a dumpling (literally, a ball or turd). Recipes mentioning noodles appear in German as early as 1480, but at that time, the term applied to any sort of doughy addition to a boiled or baked dish, whether a shaped dumpling or thinly sliced noodles. The dough could be rolled, pressed, shredded, cut, chopped, stretched, or shaped into small “buttons”—all of this was included in the word *Nudel*. The oldest German lexicons define *Nudel*

Three examples of a *Nudelholz*, an old tool for cutting pasta into thin strips by means of a ridged rolling pin. Made in southwest Germany, circa 1850 to 1870. This very ancient tool dating to Roman times was used in traditional culture to cut pasta or pastry into strands resembling modern linguini. ROUGHWOOD COLLECTION. PHOTO CHEW & COMPANY.

as a dough dish composed of wheat flour, butter, and milk. This paste is then boiled in water. There is no mention of eggs—eggs do not appear in noodle recipes until the 1600s. However, because the dough was made with white wheat flour (a luxury), the *Nudel* was at one time a food denoting high economic status.

Conceptually, the *Nudel* of Northern Europe differs from Italian pasta in that the enriched dough is not dried for later use, but rather cooked the same day it is made. The high fat content would probably preclude long storage because noodles are generally made with egg yolks, butter, and other unstable ingredients. Because of these rich ingredients, the German *Nudel* was not viewed as appropriate fasting food by strict Roman Catholics, although noodles of all sorts were indeed treated as meat substitutes. The cost of the ingredients alone set noodle dishes apart as special occasion or festive fare even in the late eighteenth century.

Earlier medieval sources are consistently clear in categorizing this type of food as something found in the invalid cookery of hospices operated by nunneries or monasteries. As a branch of invalid cookery, noodles were generally served with hot milk or cream depending on the patient's condition. Otherwise, noodles were a special-occasion food eaten only by the well-to-do as part of a larger menu, such as a side dish with a roast of meat. The concept of the noodle as health food survived in the once popular recipe for *Nürnberger Nudlen*, one of the most commonly cited sickroom recipes in old German medical literature.

By the seventeenth century, the noodle had evolved into three broad types in German cookery: flat noodles rolled thin and cut into various shapes (most often thin

strips), shaped noodles or dumplings, and yeast-raised noodles as in the case of South German *Dampfnudeln*. This last dish is prepared by steam-baking balls of yeast-leavened dough in a heavy iron skillet.

There are also a large number of specialized terms associated with noodle making. Among these are *Nudel-teig* (the dough from which any sort of noodle is made), *Nudelholz* (a special rolling pin for cutting the dough into strips), and *Nudelspritze* (a press for squeezing noodle dough into strips or strands, especially for *Nürnberger Nudeln*). Cristoforo Messisbugo illustrated a *Nudelholz* under the rubric *ferro da maccheroni* in his 1549 work on Italian Renaissance cookery. This tool was widespread in Europe, and its origin cannot be pinpointed.

The general presumption among German food scholars is that noodles (under a wide variety of names) were present in northern Europe during the early Middle Ages. Various methods of preparation, such as serving them with fried bread crumbs, may also be quite old. There is no evidence suggesting that the idea came from medieval Italy. In fact, the German noodle can be traced to the pre-Christian era, since pastry wheels and rolling pins for making noodles have been found in numerous Roman archeological sites north of the Alps. Yet the question remains whether these tools were used for making dried pasta as known to the Italians, or the richer noodle known later to German-speaking countries. It is quite possible that the Romans knew both types.

The *Nudel* appears to have entered English during the Georgian period, perhaps owing to the fact that the Hanoverian monarchs were German. The word was transliterated into English as *newdel* and noodle. The latter spelling is now the accepted form. In eighteenth-century England and America, the noodle was associated primarily with one dish: noodle soup. This is a preparation in which strands of freshly made noodles are boiled in meat stock, sometimes with the addition of small meat dumplings. This became a ubiquitous working-class dish by the nineteenth century.

The center of noodle cookery in America was the region settled by the Pennsylvania Dutch and the thickly settled German districts of the upper Midwest. In the German-American community, noodle dishes were generally reserved for Sunday dinners due to the amount of work required to make the dough. Additionally, the egg whites left over from noodle making were normally turned into sponge cakes—another special occasion dish. The Pennsylvania Dutch developed a number of interesting noodle recipes, including saffron noodles for boiled Sunday chicken, and a noodle dessert made with walnuts, sugar, and cinnamon.

By the mid-nineteenth century, noodle cookery became associated with regional peasant fare in Germany. German Romanticism elevated the noodle to an icon of German ethnicity, with the result that we see it everywhere today as a symbol of German cooking.

**NORDIC COUNTRIES.** The Nordic countries—members of the Nordic Council—are Finland, Iceland, and the Scandinavian countries (in a strict sense Norway and Sweden—the Scandinavian Peninsula—but generally this group includes Denmark as well). Finland is in many ways different from the other Nordic countries because its language is of the Finno-Ugric group (related to Estonian and Hungarian). The languages in the other countries belong to the Germanic group, and Swedes, Danes, and Norwegians understand each other when they talk together. The Icelandic language has closer ties with Old Norse. In the circumpolar areas there is an ethnic group of about around 50,000 people called Samis (often called Lapps, a designation they consider derogatory) who use a Uralic language, in addition to the language of their state (Norwegian, Swedish, and Finnish).

Many parts of Norway and Sweden consist of mountains, valleys, and enormous forests, while Denmark's highest point is less than two hundred meters above sea level. Denmark is smaller than Norway and Sweden, but comparatively it has much more cultivated land. Iceland, with its glaciers, hot springs, volcanoes, and large areas of barren land, is only populated along the coast, and fishing has always been important there. Finland, "the land of a thousand lakes," is a country of forests crisscrossed by rivers and lakes.

Sweden and Denmark are old independent kingdoms that historically have had strong aristocratic cultures. Both Norway (independent since 1905) and Iceland (independent since 1945) were ruled by Denmark for centuries, and the culture imposed by Danish or Danish-educated civil servants is still a part of the heritage in those countries. Finland, first under Swedish and then under Russian rule, gained its independence in 1919 and is also marked by the traditions of its former rulers.

The Nordic countries were mainly agricultural societies (although fishing was also important) until the last part of the nineteenth century, when industrialization marked a shift from rural to urban dominance.

The Lutheran religion was introduced in the middle of the sixteenth century, and this is still the religion of the majority of Nordic people, even though church attendance is relatively low and secular ideas dominate most fields. A Greek orthodox minority lives in Finland.

It is possible to draw a line between a northern area, which comprises Iceland, Norway, and the north of Sweden, and a southern area, including Denmark and the south of Sweden, which has ties to northern Germany and the Baltic. The west (in particular, the southwest) of Finland has strong ties to Sweden, while in parts of eastern Finland there are many similarities with Russian traditions.

### Nordic Diet and Food Distribution—Sell the Best, Use the Rest

In general, diet in a region depends on what kind of food a region produces. For example, in the Nordic countries people along the coast eat more fish, people in the mountains eat more milk and cheese from sheep and goats, and people in the lowland plains eat more meat and bread. Yet a little more than one hundred years ago, many agricultural products were not only seen as food but also as money. Social conditions were such that much of what the farmers and peasants cultivated and caught was used in a barter economy to obtain other necessary goods (such as salt, spices, and special tools).

The Nordic elite had strong ties to their counterparts abroad. The aristocracy in Sweden and Denmark, the civil and ecclesiastic administrators in Norway, and merchants in the many ports along the Atlantic and Baltic coasts followed European habits and fashions and wanted fresh and exclusive food. Many of these people were rich landowners with lots of livestock; thus they could afford to have fresh meat at all times. They slaughtered animals regularly and had cooks to prepare different dishes at their request. The wealthy also had poultry, geese, turkeys, and sometimes fish ponds on their estates. They also had regular delivery of game, fish, and wild berries from the forests. Poor people picked lingonberries (*Vaccinium vitis-idaea*), bilberries (*Vaccinium myrtillus*), and in the north the yellow cloudberries (*Rubus chamaemorus*), which they sold to the upper classes, who used them for

fruit drinks or for jams and jellies to go with roasts. Game was a privilege of the aristocracy in Denmark, as it was in most of Europe, but in the big forests of northern Scandinavia, hunting was free for everyone. Among the European nobility, the prestige of using wild animals as food was very high; this was also true in the upper classes in the Nordic countries, and very often the wealthy in these countries would buy game sold by poorer countrymen. When the smaller farmers and peasants slaughtered their domestic animals, they put aside the best cuts of meat and sold them to the manors, to the butchers in the towns, or to the ironworks where there were many foreign engineers and specialists who preferred this kind of food. In this way farmers received a certain amount of necessary cash. If a farmer had a goose or two, he would sell them, and if he had hens, he would sell the eggs. One of the most important dairy products, butter, was a means of payment as well as food.

### The Food of the Elite—More European than Nordic

Even if the Nordic countries were sometimes considered the Ultima Thule (the northernmost part of the world fit for human habitation) by people farther south, they were never isolated from the European continent. The well-known Viking raids during the Middle Ages were quickly followed by diversified commerce. Luxury products began to be imported, and there are even two Danish cookbooks from about 1300, among the earliest manuscripts of this kind in Europe, that exhibit clear

A Swedish breakfast buffet at Grinda, Sweden, featuring a variety of flat breads, pickled fish, cold cuts, and cheeses. © Bo ZAUNDERS/CORBIS.

influences from Mediterranean cuisine. German and French cookbooks were translated into Nordic languages in the seventeenth century: a Swedish edition of the famous *Le cuisinier françois* was published in 1664. This means that many of the dishes consumed in the Nordic countries were not too different from what was being eaten elsewhere in Europe. However, certain national specialities were still popular. In the eighteenth century, Swedes served the hors d'oeuvres at a so-called brandy table, which was often placed in a separate room from the dining room. Many foreign travelers in Sweden reported a habit of eating bread, butter, and salt fish before the meal and swallowing it down with glasses of brandy. The similarities with the Russian *zakuski* tradition seemed evident, but no one has resolved the issue of which tradition influenced the other.

Some of the game was unique to the Nordic region, particularly reindeer, but also elk, capercaillie, hazel hen, and black grouse. The upper classes valued fresh fish very highly, but they also consumed lots of dried, salted, and

smoked fish. Salmon was considered a great delicacy, as were oysters, mussels, lobsters, and eels.

Fresh fruit and vegetables were granted much prestige in upper-class circles, and many different species of produce were imported or grown on experimental farms in the eighteenth century. Menus from that time indicate that asparagus, artichokes, and pineapples were popular items. In general, people stuck with cabbage, onion, carrots, and other roots, but they generally considered vegetables an "animal food" and not proper nourishment for manual workers. A study from the 1890s by Amund Helland that compared food habits in Norway with those in Paris showed that the Norwegians ate 10 kilograms of vegetables per head per year, while Parisians ate 118 kilograms.

### The Food of the Lower Classes—"Humble Pie"

Since the best cuts were generally sold, offal and the less desirable parts of the animal were the most-used cuts of meat, especially among poor farmers. People always used the offal efficiently, for example, it was often minced and put into sausages or similar casings. Blood was used to make puddings, sausages, and other dishes. When making sausages, people also put grain or flour, salt and pepper, and sometimes onion in the casings. These blood dishes were in use in all the Nordic countries, but not in the eastern part of Finland, where many people belonged to the Orthodox Church.

Newborn calves were a special case. Calves were born at different times throughout the year, and the elite fattened them for some weeks and used them as roasts. However, there are accounts of a more popular and simple preparation dating from seventeenth- and eighteenth-century Norway. Ordinary people would not have the means to feed a calf in winter, so the whole newborn animal was boiled, the bones and hairs sifted away, and the remaining substance, a sort of jelly, eaten at once or kept for later use. The fat meat from the head of pigs and sheep was used in dishes such as *sylte*, which was more in keeping with the German tradition (*Sülze*) than in the French (*fromage de tête*) or English (brawn). *Sylte* was spiced with pepper and clove.

Different kinds of fat were also important ingredients in very simple, popular dishes. Some of them were dumplings, where the fat from the slaughtered animals and poultry was mixed with flour. They had many local names (*klubb*, *kams*, *klot*, *palt*, *kumle*, *kumpe*, *ball*) and corresponded roughly to the Central European *Knödeln* and *Klöße*. The flour was mixed with leaf fat from domestic animals, as well as with fat from seabirds, seal blubber, and roe and liver from fish. The fishermen in the north mixed cod liver and roe with flour, spices, and raisins and put this mixture into the cod's head or sound (air bladder) and boiled it in water. In some cases parts of the fish itself, fresh or salted, were added to this mixture, and potatoes were partly substituted for the flour. Before the use of forks and plates, slices of the ball were cut with a

knife and placed between two bits of crisp flat bread, similar to the way one eats hamburgers today. A special type of ball was made from the blood of domestic animals, but more often this mixture of flour, blood, and some spices was made into sausages or baked into a soft flat bread.

Another way of combining fat and cereals was the *mölje* (jumble): crisp flat bread was broken into small pieces and put into a bowl with the liquid from boiling meat liver. Fishermen ate a *mölje* with crisp flat bread and cod liver. All these examples show an efficient use of all the parts of animal or fish products that were not sold or saved for important occasions.

In Finland there were and are examples of a special combination of flour with fish or meat, pies, and pasties. In the east they are called *piiras* or *piirakka* (Russian *pirog*) and *kukko*, which is a big pie with dough all around. *Pirog* is normally smaller than *kukko*, and if it is big, the filling is exposed with no crust on top. The filling in *kukko* may be meat, potatoes, cabbage, and turnips, but it was originally fish. In the west, along the coast, a similar pie had the name “herring cake.”

### Meat and Status

As in most societies, meat held more prestige than other food in Nordic countries, but there were also differences in the evaluation of different kinds of meat. The importance of pork in older times could be seen in the Swedish and Danish terms used for it, *fläsk/flaes*, which are similar to the German *Fleisch*, which is a generic word for “meat.” Today beef is more expensive than pork, but in the Middle Ages pork was much more expensive than beef and mutton if one calculated its average price by weight.

As a general rule, it is possible to say that swine dominated the meats of the south for a very long time, while cattle were more important in the north for several reasons, not least of which was that they provided hides and milk products. The tough meat from old and worn out cows and oxen was not used in steaks and roasts; rather, it was boiled in a pot with cabbage, groats, roots, and available herbs and spices. This meat was normally salted and put into water before it was boiled, so the salt could be extracted and the meat would soften. Mutton was also boiled this way. One common word for these dishes was *kål* (cabbage), which was used whether they contained cabbage or not. The Old Norse word, however, was *sodd*, which simply means “boiled.” The use of this word is probably a sign of how old this dish is.

Mutton had played a very important role in Nordic countries, but the number of sheep—and goats, the even less prestigious domestic animals—has gradually diminished in Nordic countries during the last few centuries. Mutton was often eaten uncooked, since it had been dried, salted, and occasionally smoked. In general the meat was very seldom eaten fresh, except among the elite—a fact often commented upon by foreign visitors. This was, especially in the northern regions, a result of

the climatic conditions. The summer season during which animals could graze was very short. During a winter with deep snow, feeding animals required a lot of fodder. Animals that were raised only for meat production were slaughtered after the summer, when they were at their fattest. In order to preserve the meat, the farmers had to dry, salt, or smoke it. Pork was often kept in brine.

This preserved meat could be kept for years: it was considered a symbol of wealth to have stocks of meat at the *stabbur*, a special storehouse built on pillars. From Denmark we know of the tradition of *gammelmadsfad* (plate of old food) or *saltmadsfad* (plate of salt food), which involved a big platter with all sorts of smoked and salted meat that could stand on the table for weeks. In Norway reports from wedding feasts in the eighteenth century tell about plates with old food that were put on the table but not eaten—they were only used as a decoration year after year.

### Fish Consumption and Preservation

In the United States, especially in the Midwest, the Scandinavian population identifies with a peculiar dish: *lutefisk*. This dish has a jelly-like consistency and often a yellowish color. The dish is generally unpopular among people who have never tried it. The same holds true in Sweden, where *lutefisk* is considered a national dish.

The best raw material for *lutefisk* is the dried cod from the northern coast of Norway, where the air is rather cool. The *tørrfisk*, or stokfish, holds almost no humidity, lasts for years, and has been exported to Europe since before the year 1000. The fish had to be beaten or softened in water before they were cooked. In the late Middle Ages a special method emerged for the preparation of this dish: a potash lye or soda was put in the water to help soften the fish, and the result was *lutefisk* (lye fish). The oldest sources for this method are found in Sweden and Germany, but there are also recipes in early Spanish and French cookbooks, so the dish may have existed elsewhere.

Drying is probably the oldest method for fish preservation in Scandinavia, where all sorts of fish were cleaned and hung up to air dry. Even herring was dried, but it did not last as long as other fish because of its high fat content. In the north of Sweden and Finland, pike and other freshwater fish were dried. Salmon that could be dried, salted, and/or smoked held the most prestige.

Cod and other white fish were also salted in brine. This was the most common way to preserve herring, and salted herring has been an important part of Scandinavian diet for centuries. It was either eaten cold or grilled, normally with bread or porridge, and later with potatoes.

High-quality salt was expensive, but necessary for a good product. Among ordinary people who had little money for salt, a special method of preservation developed for herring and some freshwater fish. The Swedish term *gravlaks* (buried salmon) dates back to the Middle

Fresh salmon on display in the fish market at Bergen, Norway. © WOLFGANG KAEHLER/CORBIS.

Ages, when the fish, sometimes lightly salted, was buried in the ground or in a barrel. It could be kept for months because of the slow fermentation that occurred. The result was soft flesh, but also a sour taste and a strong, unpleasant smell. In Sweden this method is still used to make the sour *strömming*, a herring from the north of the Baltic Sea (the Gulf of Bothnia). People in Norway also used herring, but today they mainly use trout from inland rivers and lakes. Icelanders use the flesh of the *bákurl*, a species of shark. The same fermentation technique exists in other circumpolar areas, and it is related to the old Roman *garum/liquamen* process.

In the modern version of *gravlaks*, the salmon has only gone through the early stage of the chemical process, where enzymes soften the flesh. Filets of salmon, with salt, sugar, pepper, and fresh dill spread between them, are placed under heavy weights for a couple of days in a cool place. This method of fermentation probably developed within the upper classes at a later time than the original method.

### Milk—A Way of Life

Milk was extremely important in the northern part of Scandinavia, Iceland, and parts of Finland. In this area's tough climatic conditions, sheep and cattle were raised partly for hides, partly for food, but first and foremost for milk. In Iceland *skýr*, a curdled milk from sheep or cows, is considered a national dish.

One of the most important dairy products, butter, was so important in the northern countryside that it was used for hundreds of years as a symbol of wealth, partic-

ularly at weddings, where pyramids of sculptured butter were raised at each end of the table. The butter was formed in special wooden cases with patterns of flowers or animals. Folk museums display these butter sculptures as examples of popular art.

For the past several centuries, the elite of the Nordic countries have imported cheeses from Holland and Switzerland. These cheeses are made in the general European fashion by adding rennet to the milk. This was a different tradition from the one in the northern regions, where the milk was coagulated in a process caused by lactic acid. Some of these cheeses were sweet, a little like puddings or desserts, and others were made from sour milk, usually from a cow, but also from sheep and goats. One of the most famous and prestigious cheeses was the *gammalost* (old cheese), which was dark brown and rather hard with a grainy texture.

Milk was almost never drunk sweet; rather, it was made into different sour-milk varieties. A very special type was the "long milk" or "thick milk" that would stay fresh during the summer. It was also called *tettemjolk* in Norway and *tätmjolk* in Sweden after an herb (*Pinguicula vulgaris*) that was put into the milk that was said to cause the souring process. Today many people dispute the role of the herb: the process also starts when a little old milk, containing certain bacteria, is put in the kettle with the new milk.

In the northern areas, milk had to be substituted for beer as a common drink because of the low production of grains. The daily drink of ordinary people was *blanda*, which was sour whey blended with water. The inventive

use of whey, the substance remaining after cheeses are made, is specific to the northern regions. It might be boiled into a sort of soup and eaten together with bread (sour milk was also used this way). Whey might also be boiled for hours until it became a thick substance. This was then put into wooden cases to cool and, when finished, looked like brown bricks. This “cheese” was either made from the whey of sweet or sour milk (the sour being the cheapest) and was spread on flat bread instead of butter by the poor and servants.

### **Bread—Flat, Soft, Hard, Sweet, Dark, White**

The cold climate and the meager soil in the north made it difficult to grow grains other than oats and barley; since these do not contain gluten, they could not be used for leavened bread. The result was different sorts of flat, thin bread, specialties of the northern regions. These stood in contrast to the leavened rye bread in the southern part of Scandinavia, Denmark, and the Swedish region Skåne (which was part of Denmark until the seventeenth century). In Finland a dividing line can be drawn between the west and north, where different sorts of hard breads were baked, and the east, where soft rye bread was common.

The Danes, like the German and Dutch, had *smørrebrød* (butter bread), a dark rye bread served with butter and cheese, cold meat, sausage, liver paste, or other delicacies (internationally known as “open sandwiches”). While the flat bread in the north was baked on griddles (iron plates), bakery ovens were more widespread in the south, and the Danes often bought their bread from the baker. The Danish bakers, organized in guilds with strict rules, were obliged to have certain products ready at all times: white bread, coarse rye bread, and *skønrogger* (from sifted rye), in other words, alternatives for all classes of society. The status of bread had to do with the kind of flour used: for example, during festivals, the elite would eat only white bread made from wheat flour. This bread was best when fresh, but most people would let their bread dry out, which made it more economical since it would last longer.

The Swedes are especially known for their sweet and spiced breads. One French diplomat remarked as early as 1634: “The bread had a terrible taste, made as it was with wort and sweet fennel.” This was the dark *vörtbröd*, made with beer wort, molasses, spices, citrus peel, and raisins. These sweet breads were earlier a luxury or used only for festive situations. The expression “sweet bread days” meant (and still means) good times.

### **Porridge—For Hunger and Luxury**

Porridge is an old dish, perhaps more ancient than bread, and it has been used in many cultures. Flour mixed with water (“water porridge”) was the simplest variety and was long thought to be a synonym for poverty. Scandinavians also mixed the grains with milk, cream, or whey. As was already mentioned, whey soup was eaten with bread. Milk

made the porridge more attractive, and during annual festivals and rites of passage it turned into a luxury dish, *rømmegrøt* (sour cream porridge), with the addition of cream or butter. In modern times, porridge is more like a pudding made from rice and milk and is often sprinkled with sugar and cinnamon, but the *butterye* (a lump of butter in the middle) is still a relic from the past.

In early modern times and up until the nineteenth century, rice was a luxury that very few could enjoy. It was more common in Denmark, where they also ate porridge from *maiz* (corn), buckwheat, and pearl sago. Oats were not popular in Denmark unless they were made into groats, which were easier to digest. Danish porridges were often boiled with sweet milk, but in Skåne (southern Sweden) there is also a tradition of serving beer on porridge. In Denmark they have *øllebød* (beer bread), which is rye bread that is diced and boiled in beer with sugar and lemon peel. In characteristically Norwegian style, when *øllebød* was introduced there it was made with a mixture of beer and milk.

### **Nordic Drinks**

*Blanda*, sour whey or milk mixed with water, was previously mentioned as a daily drink in northern regions. But beer production occurred everywhere: a very light and simple beer for daily use, and stronger brands for festivals and special occasions. Since the Middle Ages, more exclusive beers were imported from Germany, and the more affluent of society imported mead (made from honey). Grapes have never been grown in the Nordic countries, but wine has been imported since the time of the Vikings, especially after clergy with southern European roots established churches and monasteries in the region.

Ever since the eighteenth century, *akevitt*—brandy made from grain—has become more and more common. It is considered good for health and physical strength. Farm hands received a shot of *akevitt* when they started work at around 5:00 A.M. and when they began to tire in the afternoon. *Akevitt* was also used with sugar and spices in drinks, but imported brandy was preferred for this use. The introduction of potatoes in Nordic countries offered new and cheaper possibilities for *akevitt*, and the production and consumption led to widespread alcoholism in the countryside in the early nineteenth century. However, things began to change when popular temperance and abstinence movements emerged in the second half of the nineteenth century. The government introduced restrictions on distillation of alcohol, and coffee gradually replaced beer and brandy as the daily restorative drink.

### **The Sami Diet**

A portion of the Sami people lived as nomads with their flocks of domesticated reindeer, but some also lived on the coast (the sea Samis) and were more residential in nature. Their diet placed an emphasis on meat and milk. The Samis ate meat from many wild animals: bear,

otter, hare, marten, and wolverine, but never fox and wolf. Contrary to the rest of the Nordic population, they had no prejudice against horseflesh, which they ate dried. Their main source of food was reindeer, and they used every bit of it: the head, heart, and tongue were delicacies of great value. They never roasted fresh meat, but always boiled it. They preserved much meat for future use by drying—they never used brine. Dried meat was easier to transport. Also, blood was freeze-dried and then ground into a powder. Fat was appreciated, especially the rich rectum fat that was dried and used as cream in coffee, when this drink was introduced.

Among the Samis there were strict rules as to who could eat what. The heart and the genitals of the buck were reserved for men. Men also had the responsibility of preparing meals, particularly if the meal involved meat from reindeer and bear.

Fish was important for the Samis along the coast, but people also fished in the rivers of the great plains. The fish was boiled or dried for later use, and the roe was considered a special delicacy.

In general, bread has no tradition among the Samis, the exception being the sea Samis. For the nomads, carrying bread or flour and purchasing flour was no easy task. When bread finally was introduced, it was almost always unleavened.

Butter, cheese, and boiled dishes were made from milk. Herbs and berries were used instead of spices. The usual drink before coffee was water, sometimes mixed with male (sap from birch trees). The main meal was in the evening, and it always consisted of meat or fish. For lunch a lighter meal was common, such as soup or reindeer meat or, in summer, a cheese gruel.

### A New Diet in an Urban Society

During the late nineteenth and the early twentieth centuries, the Nordic countries went through a process of urbanization, industrialization, democratization, and the emergence of stronger commercial links to the world outside. Many of the old traditions in meat preparation were changing. For example, the introduction of meat grinders made it possible for most social groups to mince meat. In earlier times, this was a privilege of rich houses, because it demanded servants who worked for hours with knives. Now everybody could make the meatballs that were and still are extremely popular national, everyday dishes in several of the Nordic countries, where they are referred to as “mother’s meat balls.”

A special dish that is less common today because it demands so much work to prepare is stuffed cabbage—minced meat in cabbage leaves (instead of the Mediterranean version with grape leaves). An unsubstantiated legend claims that the Swedish recipe, called *dolma* (a Turkish word), was brought to Sweden by King Charles XII, who spent several years in Turkey after his defeat at Poltava.

In general, with the advent of urbanization, the tendency went in the direction of more fresh food than before. In addition to the balls made of minced meat, cutlets of pork, sausages, chicken or veal fricassees, roasts, and steaks also became very popular. In Denmark the “old food platters” were replaced by “roast platters.” The introduction of the kitchen stove was instrumental in this change.

In Norway, where there was no local tradition of leavened bread, the spread of bakeries and bakery ovens in the late nineteenth century led to the emergence of a great variety of breads. Apart from the wheat and rye bread known in Denmark, healthy new alternatives were offered, such as *kneippbrød* (after the German doctor Sebastian Kneipp), *grahambrod* (after the American dietician Sylvester Graham), and later whole-meal breads of different recipes.

As in so many countries, butter faced competition from the new artificial substitute, margarine. Many farmers replaced butter with margarine and received extra money to buy salt, spices, coffee, sugar, and other foreign products. This happened at about the same time that the entire system of dairy production went through a fundamental change. Instead of making different dairy products on the farm, farmers started to sell their milk to the new factories where butter and cheese were produced with modern techniques. This practice also followed a shift in cheese preferences. During the nineteenth century, Swiss and Dutch cheeses grew more popular, and the Nordic countries imported both cheese and dairy specialists from Gouda, Edam, Leiden, and Switzerland. The specialists trained local dairymen to make cheese a new way, and one of these cheeses, the Norwegian Jarlsberg, has been a success in the world market.

During the nineteenth century, coffee became the daily drink everywhere. It spread from the big cities to the countryside and from the elite down through all the other levels of society.

Potatoes represented the most extraordinary shift in food consumption, with a complete breakthrough occurring during the Napoleonic Wars. After that time, preparing the main hot meal was barely possible without boiled potatoes, the basis of Scandinavian cuisine. The nineteenth century was also a great time for herring catches, and the low price of these two products led to the expression “salted herring and potatoes,” meaning a poor man’s food or *husmannskost*. Also roast fresh herring was a very common dish among ordinary people. However, herring was also present in the *smörgåsbord*, which has been popular in Swedish restaurants and hotels since the late nineteenth century. Around a big brandy pot with taps for different brandies and *akevitts* were several sorts of cured herring, sardines, marinated sprats, smoked eel, grilled eel, eel in jelly, pig trotters, brawn, sausages, and later also *gravlaks* and smoked salmon. Today the *smörgåsbord* is not only an introduction to a meal, but it can be a full buffet lunch or din-

ner, complete with hot dishes (such as meatballs and steaks with onion). Dessert consists of different kinds of fruits, sweets, and cakes.

### Food and Feast

Special occasions in life and rites of passage have always involved special dishes. The main objective has been to serve something special that sets that day apart from the rest. In rural societies, where resources were not always abundant and cash flow was low, a system of gifts emerged. Guests brought food to weddings and funerals, often butter and rich cheeses, which were all put on the table and then brought back if they were not finished. In the twentieth century, this custom changed with the advent of a more urban society and smaller families. New habits spread gradually from the aristocracy to the middle classes and then to the whole population. The *pièce de résistance* at special occasions, in most cases, was a roast.

Different regional traditions have developed around religious holidays. Among the many old traditions tied to the long Lenten period before Easter, only the sweet rolls with whipped cream still exist. A special Easter dish in Finland originated as a Lenten dish among Catholics in the southwest, but it has since spread to the whole country. *Mämmi*, a dark brown porridge-like substance made from malted rye and baked in the oven in boxes of birchbark (today cardboard), is served with thick cream and sugar.

Feasts for saints were much more important in earlier times, but the roast goose of St. Martinmas in November has survived in Denmark and in southern Sweden, where it is accompanied by *svartsoppa* (black soup) made from goose blood and giblets. On the thirteenth of December the Swedes celebrate Sancta Lucia with elements from an ancient regional feast. Young girls in white robes and candles on their heads march through the streets singing an Italian song and handing out *lussekatter* (Lucia cats), which are small saffron cakes. A

special feast without any connection to religious traditions is held every August when crayfish are in season. Crayfish parties are merry events that involve paper hats, special plates, and lots of singing and drinking. The crayfish are boiled in dill and served cold. Swedes eat more crayfish than most people in the world. Most of the crayfish are wild, but there is an increasing farming industry in addition to the importation of about 3,000 tons of crayfish every year.

The Icelandic Thórablot in January is named after the Norse god Thor (Thunder). *Blót* was a religious ceremony that involved offerings to the gods and reputedly much eating and drinking. The food is *búkarl* (sour buck's balls), boiled sheepheads, and *hangikjöt* (smoked meat of lamb).

### Christmas Celebrations

The one occasion in which the Nordic population as a whole still maintains traditions is Christmas. At this time people eat large quantities of meat. Many baked items are prepared exclusively for Christmas and are called Christmas cakes, of which there are seven required types.

The traditional Christmas meal is generally served on Christmas Eve, but the food is very different from country to country. In Denmark the traditional main dish was goose, as in Hans Christian Andersen's story "The Little Match Girl." In recent times, duck has been substituted for goose, but the stuffing is the same: apples and prunes. Dessert is a sweet rice pudding made from rice boiled in milk, with almonds and whipped cream added. Christmas Day in Denmark involves different traditions, but very often roast pork is served.

In Norway there are regional differences: roast rib of pork with sauerkraut is served on Christmas in the east, boiled cod is served in the south, and *lutefisk* is served in the north. The specialty of the west is *pinnekjøtt* (stick meat), a dried, salted, and sometimes smoked rib of lamb, which is put in water during the night so some of the salt is extracted and placed above steam for several hours. Tradition says that during the steaming process the long ribs should rest on sticks of birchwood. It is served with mashed turnips. Boiled potatoes accompany all the aforementioned dishes.

In Sweden *julskinka* (Christmas ham) is obligatory, but it is only one of the dishes served at an expanded *smörgåsbord*. Swedes eat *lutefisk* and rice porridge during the Christmas period. Another traditional element of this feast is the *vörtbröd*, which is dipped in the broth where the Christmas ham has been boiled, and a special hard Christmas bread that is a little softer than the crisp rye *knäkkebröd*.

*Julskinka* is also a main dish in Finland on Christmas Eve, but there it is often smoked in the sauna. In addition, the table holds sausages and the traditional oven-baked dishes in earthenware, called "boxes." These

boxes contain liver, potatoes, turnips, and so forth. This kind of meal is also typical for weddings and other big events, although the *julskinka* is then often replaced by a roast of elk or other game. Dessert is a thick soup of dried fruits, also a very popular dish in Finland. Before this rich meal the Finns eat a hot lunch with *lutefisk* and rice porridge. In the southeastern part of the country, the *pirogs* will be on the table for Christmas.

On Christmas Day in Iceland the traditional dish *hangikjöt* is served and eaten cold. On Christmas Eve in Iceland people have no set tradition, but loin of pork and grouse are fairly common dishes.

### Toward an International Cuisine?

Since the start of the twenty-first century, many old Nordic traditions have begun to change. Food consumption and food habits in Nordic countries today have been strongly influenced by international trends such as fast food, ethnic cuisine, and gourmet-restaurant culture. This development is a break from what was, until the late twentieth century, the general fare for the majority of the people in this region.

The use of minced meat is no longer limited to meatballs, as it is eaten with spaghetti, in lasagna, on pizzas, in tacos, and in pita breads. This trend also implies a reduction in the consumption of boiled potatoes. However, there has been an increase in consumption of *pommes frites* (fried potatoes) and potato-based snacks. This has partly to do with the strong increase in fast food (so-called "street kitchens"), where earlier only hot dogs were sold, but which now offer hamburgers, grilled chicken, and other dishes.

Different types of fast food or ready-made dishes are also being used for the main hot meal, served in the afternoon after parents come from work and children from school. In Sweden and Finland they also eat hot meals for lunch, either in cantinas, cafeterias, or street kitchens. Many Danes and Norwegians, who earlier enjoyed their lunches of open sandwiches, are now choosing hot fast food or cold salads for lunch. Open sandwiches are also being challenged by new varieties made from French baguettes or Italian ciabatta. Whereas the extravagant open sandwich had to be eaten on a plate with a fork and knife, the baguette and ciabatta sandwiches, with fillings of ham, cheese, or shrimp, can be taken away and eaten while standing or walking; at the same time, these sandwiches have more substance than the original, less substantial English sandwiches.

Drinking habits are changing in the direction of a more southern European style. Alcohol is still important for festive situations, but wine consumption is increasing rapidly compared to consumption of beer and strong liquor. Coffee is still brewed and drunk in the same way (what is often called American coffee), but new coffee bars are growing up all over, offering cappuccino, cafe latte, and espresso.

Important factors behind these changes are increased wealth and prosperity, travel by Nordic people to Mediterranean countries, an influx of new products from southern Europe, Africa, Asia, and the Americas, and the new urban lifestyle promoted through mass media. However, the break with tradition is not complete, because the new trends are mainly affecting smaller groups, such as urban, educated young people with relatively good financial freedom. This probably indicates that more pronounced changes will take place in coming generations.

Henry Notaker

**NOSTALGIA.** The elusive word “nostalgia” is formed from two Greek roots: *nostos* (“return home”) and *algia* (“pain”). The *Oxford English Dictionary* defines nos-

algia as “a form of melancholia caused by prolonged absence from one’s home or country; severe homesickness.” In her remarkable book *The Future of Nostalgia*, Harvard professor Svetlana Boym says that the word was coined in 1688 by the Swiss doctor Johannes Hofer to identify the homesickness of Swiss soldiers who reacted physically to the hearing of certain folk melodies and the eating of rustic soups while on missions away from home. She centers her study on the effects of leaving one culture and residing in another, and of exploring cities rich in archaeological layers of memory. She also distinguishes nostalgia as either being restorative, as in recovering a lost home, or reflective, as in shaping a certain way of thinking about a particular time and place. In the latter, memory becomes a transformative and a reconstructive power.

#### The Idiom of Exile

In politics, art, music, literature, psychology, and even pop culture, nostalgia is the idiom of exile with, as Boym says, Adam and Eve as prototypes. While it may be a stretch to imagine their longing for the prelapsarian apple after they left the Garden of Eden, it is certainly true that through the years the exiles and emigrants that followed their path from their native land to another country either tried to replicate the foods of their homeland or the taste sensations of their childhoods. Almost without exception French chefs, especially when transplanted to America, nostalgically craved the simple soups, daubes, and *pot-au-feu* of their childhood. The four-star chef Fernand Point believed that his mother’s cooking was the best kind of cooking, and his disciples Paul Bocuse and Alain Chapel also went back to the simpler foods of the countryside in a movement called *nouveau cuisine* that captured immediate attention in France and abroad. Known as *cuisine de meres*, these ancestral cooking ideas perpetuated in their respective provinces fed their souls as well as their bodies. Nostalgia proved to be a powerful force.

#### Nostalgia in Literature

Literature, moreover, abounds with powerful nostalgic works like Jean Jacques Rousseau’s *Confessions* and Henry David Thoreau’s *Journal*—both motivated by early memories of a purer, more innocent, psychological, as well as physical, place to which there is no possible return except through memory. It was Marcel Proust, however, who irrevocably linked the subjective and often unreliable vagaries of memory with the particularity, sensory modality, and physical presence of food. In pursuit of vanished time, he found a transfiguring moment in the taste of a madeleine dipped in a cup of lime flower tea. Although he frequently had passed the golden shell-shaped French cookies in patisseries, it was not the sight or taste of the madeleine itself or even the tea, but the sensation, or Baudelairean correspondence, that immediately took him back to those Sunday mornings in Combray with his Aunt Leonie when he was a treasured child and not the world-weary adult he had become. The remembrance of

The old New England kitchen is evoked in this circa 1900 photograph of Quaker women gathered around a Nantucket hearth. Nostalgia for old-time foodways is everywhere evident in this picture, although distorted by Victorian notions about the past. A foot warmer is prominently displayed on the tea table instead of under the feet of the elderly woman facing the hearth. Spinning wheels abound, and the woman on the left is wearing a bonnet, which was only worn in public, not in the house. Finally, in spite of the clutter of utensils on the hearth, there is no fire. ROUGH-WOOD COLLECTION.

food and, more specifically, the eating of a meal became a trigger point to his self-discovery.

Memories of a wistfully longed for earlier time exist not only in novels, but also in the various autobiographical forms. In *Memories of My Life*, Auguste Escoffier remembered his childhood in Villeneuve-Loubet and wrote about watching his grandfather toast bread and spread it with a particularly strong local cheese called *brousse*. One Sunday, when the young Escoffier tended the fire while his grandfather went to church, he prepared the same cheese toasts, which he then savored with a glass of sweet wine. Seen from the perspective of the mature and successful chef he had become, the incident was but one example of how easy it had been for him to satisfy both his curiosity and his gourmandise. In other personal narratives, odors rekindled memories of other kitchens. Writing about growing up in his mother's boarding house in a *Feast Made for Laughter*, Craig Claiborne described the smell of chopped onions, celery, green sweet peppers, and garlic sautéing together in butter or oil. The smell pervaded the kitchen and in his memory seemed the basis for seemingly hundreds of dishes his mother prepared and that he always identified with "southern cooking" and home. And in James Beard's *Delights and Prejudices*, beach breakfasts of sautéed razor clams gathered along the Oregon coast vie with the Welsh rabbit of the family's Chinese cook to epitomize all that was wonderful about his childhood in Portland.

The sights, smells, and tastes of the holidays almost without exception also evoke nostalgia. In his testament to childhood, *My Father's Glory; and, My Mother's Castle: Memories of Childhood*, Marcel Pagnol recreated his Provençal childhood through the eyes of an aging and successful filmmaker. In this autobiography there are scenes about a small boy exploring the streets of Marseille, and about the family's trips to their rented vacation home in the hills where the young Pagnol learned to hunt, trap, and explore the caves and the forest. Neither before nor since was the Christmas holiday in that place so exciting and memorable. Thrushes that he and his friend had trapped "tumbled from branch to spit," a small pine tree from the forest occupied the corner of the room, and on its branches hung hastily assembled presents, and after the Christmas Eve meal, the family feasted on dates, crystallized fruit, whipped cream, and the *marrons glaces* that his uncle had brought from the city. Seeing his father and uncle greet each other, Pagnol felt a new emotion and as a child recognized real friendship for the first time while savoring the *marrons glaces*.

Autobiographies and memoirs that are driven by taste, by memory, and by real life communicate reality in a basic way. When asked about why she wrote about food rather than love, war, sorrow, and death, M. F. K. Fisher simply said that our human hungers for security, warmth, love, and sustenance were inseparable. And she, more than any other American gastronomical writer, combined

autobiography and her philosophy of the art of eating to create a hybrid genre called the culinary memoir. Whether she gently folded recipes into her narratives or simply explored the bliss or misfortune of family feasts, vegetable snobbism, the best oyster stew she ever ate, or learning to dine alone, she established the familiar “I myself” pattern that echoes through contemporary culinary food writing. The note of nostalgia or longing for an ideal past that can only be repossessed symbolically by familiar foods—a note that pervades the most memorable memoirs—has been given a voice in her distinctive first-person style. And the unrelenting use of gastronomy as a kind of surrogate to ease all human longings has found a varied expression in her narratives.

M. F. K. Fisher has had many imitators because the act of remembering has become a dominant part of how writers—especially cookbook authors—thought about food in the last decade of the twentieth century and continue to do so. Some memoirs have been straightforward records of the author’s life and his experience of memorable meals, and recipes have been either abundant or completely absent. In the best of these memoirs, however, the recipes have become an extension of the text. They function as a kind of chart of the emotions evoked by meals or certain moments frozen in time. Other memory-plus-recipe books have been plainly cookbooks in which nostalgia functions as a stylistic device. Headers tout Aunt Tillie’s doughnuts and Uncle Jerry’s barbecue, or evoke quaint breadboxes lined along Formica counters or that exciting aperitif sipped in a café along the Boulevard St. Germaine. Unfortunately, their authors often lack the authentic voice of M. F. K. Fisher, and their work does not resonate with the depth of continuous reminiscence.

Whether it is a once-in-a-lifetime Reine de Saba, a comforting Toad-in-the Hole, or an ordinary macaroni and cheese meal, the pleasures of the table need a writer to transcribe them, and a writer needs a sensibility that is shaped by empathy with the conditions of time past as well as time present. Nostalgia is a powerful motivator.

**NOUVELLE CUISINE.** The expression “nouvelle cuisine” has been used several times in the course of the history of cooking, particularly in France in the middle of the eighteenth century. It was introduced to subordinate the practice of cooking to principles of chemistry that were to be established by Lavoisier later on. People had mixed feelings about it: for instance, Voltaire wrote “I must say that my stomach does not at all agree with the ‘nouvelle cuisine.’”

#### Origin

Today nouvelle cuisine refers to a trend of opinion that appeared in France in the 1960s. At the time, it caught on rapidly and was a great international success. Yet, as

it got tangled up in its contradiction, it stopped being fashionable, and nowadays it has a negative connotation. In spite of that, it was an innovative and quite important movement, which brought about a revolution within the “grande cuisine” whose lessons are still present in the grand chefs’ minds.

Among the precursors of the movement were Fernand Point, Alex Humbert (who first made the *petits legumes*), André Guillot, and Jean Delaveyne, former chef at Buckingham Palace; they were those who questioned Auguste Escoffier’s heavy heritage. They rejected the overused *fonds de sauce* as well as the so-called Allemande (German) sauce, a light one, and Espagnole sauce (Spanish), a dark one, gravies that were the basis of all kinds of rich and little refined dishes whose taste was almost always the same, since the products lost their specificity when cooked. They made their sauces less rich, highlighting the freshness and the quality of the products, thus paving the way for a revolutionary generation who was to shake up the tradition.

One has to bear in mind that at the beginning, the chefs of the nouvelle cuisine were not outsiders to French cooking. On the contrary, they were the brilliant pupils of the greatest traditional chefs. The revolution in cooking came from within the Michelin-starred restaurants. Paul Bocuse, Alain Senderens, Jean and Pierre Troigros, Alain Chapel, Michel Guerard, when very young, all started studying the traditional way, a painstaking, difficult time of apprenticeship, moving from one place to another almost in the same way as the students who graduate from different universities. An important characteristic of the movement was friendship. Although French chefs are usually individualistic, even selfish, these young chefs were always in contact, telling one another of their discoveries, discussing their problems, and so on. Today, they still do it, although they themselves have become the symbols of a new tradition.

### Characteristics of Nouvelle Cuisine

Nouvelle cuisine has several characteristics. Most important were the quality and the freshness of the products chefs used. They went shopping to the market every morning and looked for the best products, and never used any preservatives, deep-frozen food, or any product that was not absolutely fresh. They did not offer a menu card with a long list of dishes that never changed, the reason being that such a long list required having a great quantity of products available. As a result the leftovers would necessarily lose their freshness and thus could not be used. Instead, they offered a reduced number of recipes that kept changing every day according to their market shopping. At the time, in Paris, this was made easier thanks to Les Halles, a huge market right in the heart of the city, within walking distance of every restaurant. Because they were looking for quality, the chefs became more and more attracted by unusual, exotic products. Foreign influences prevailed, particularly those of North Africa (Morocco,

especially), Italy, China, and Japan. In 1960 Shizuo Tsujii opened the first school of French cuisine in Japan, which multiplied the cultural exchanges between the two countries. So much so that in 2000, Alain Senderens remarked “the nouvelle cuisine is now Japanese.”

In the new style of preparations, there were no *fonds de sauces* used in the dishes any more. Sometimes, short juices, quickly made, were turned into a small quantity of sauce, which was to be served on fresh, only lightly cooked products.

The spices banished from the French cuisine since the seventeenth century were now back in use; contrary to the Middle Ages, they were no longer used in large quantities, but in small touches and only to rouse the flavors that would blend with those of the products. The effect they aimed at was to enhance the quintessence of the product, that is to say that sauces or spices were only used to bring out the product’s taste and qualities, not as a substitute for them.

The approach was similar to that of previous cuisine movements. The new chefs stressed the importance of nutrition and its consequence for people’s health. They wanted to change the image of an obese gastronome into that of the slim, smart dilettante so much in vogue in the magazines of the 1960s. For their female clients, always anxious to watch their figures, the chefs felt urged to contrive new recipes that could be delightful without being rich. Indeed, it is significant to note that the first book written in 1976 by Michel Guerard was *La cuisine minceur*.

As a result, less food was served; of course what each dish lacked in quantity had to be replaced by better quality and a better esthetic presentation. It is true that the grande cuisine had always included an element of display and ceremony: As the dishes were prepared for all the guests present, the dinners were organized as a ceremony for the whole party, to such an extent that, at the beginning of the nineteenth century, Antonin Carême defined the *pâtisserie* (pastry cooking) as a branch of architecture. Instead, the new chefs replaced the presentation of entire dishes with that of individual plates; what was considered beautiful and attractive was not the whole chicken, the whole *pate en croute*, or *baba*, but the layout of the food on each plate that the guest was about to eat. To serve the dishes, the chefs no longer enacted their ritual at the pedestal tables on which they used to carve the meat or flambé the basses. They brought each guest their own plates, with the food previously prepared. Sometimes, it was hidden under shining dish covers the waiter would take off as a surprise, once the plate was set in front of the guest. Then the guests would appraise the esthetic aspect of the layout and enjoy the all-pervading fragrances of the food.

The chefs were always in search of new products and new aromas. Similarly they also kept looking for new techniques. As they were the best technicians of their generation, they began using all the new tools available:

cutter blenders, food processors, nonstick materials, and so forth. The relationship between food and fire had become a central problem, so they started experimenting with new methods such as cooking under vacuum, microwave ovens, and steam ovens. Yet this did not mean that they ignored some of the old methods; in fact quite a number of them were brought back into fashion, for instance, the *cuisson en croute de sel* and steam cooking. Moreover the fact that they had learned how to control the use of refrigeration enabled them to use new ways of preparing the food or carving the meats, which otherwise would not have been possible.

### A Cultural Phenomenon

First and foremost, the *nouvelle cuisine* was a genuine revolution accomplished by the chefs themselves, more precisely the best of them. However, the newspapers and other media played an important part in the overall outcome. Raymond Oliver was the first to appear on a weekly TV show, which lasted for fourteen years and made him a star. Other chefs also became stars, which was seldom the case before that.

The expression “*nouvelle cuisine*” owes a great part of its success to two journalists, Henri Gault and Christian Millau (who for the first time in 1969 published the *Nouveau Guide*, followed in 1971 by the *Guide Gault et Millau*, a monthly magazine which soon became popular and had a great influence on the chefs as well as on their clients). Besides, at the time, the expression itself fitted nicely into a whole set of new trends of thought, of things or events which had appeared after World War II, for instance *la nouvelle critique littéraire* (the new literacy criticism), *le nouveau roman* (the new novel, with Alain Robbe-Grillet, Nathalie Sarraute, and Nobel Prize winner Claude Simon), and *la nouvelle vague* (the new wave) in the cinema with Alain Resnais, Jean-Luc Godard, François Truffaut, and Claude Chabrol. Traditional guides, the *Michelin* in particular, had already acknowledged the worthy chefs by giving them one to three stars: for example, Paul Bocuse was awarded three stars in 1965, Haberland, in 1967, and Troigros and Barrier, in 1968. The new *Gault et Millau Guide* quite cleverly introduced a new distinction between the *nouvelle cuisine* chefs and the traditional ones. Later on the distinction was noted by a printed symbol, the former having a red one and the latter a black one.

### Heyday and Demise

In 1973, in number fifty-four of their guide, Gault and Millau published the ten commandments of *nouvelle cuisine*, among which they advocated that one should reduce cooking time, use best-quality products and products fresh from the market, offer a shorter menu, limit the use of modern technical tools, while keeping open to new developments, do away with marinades and game hanging, cook sauces that were less rich, respect dietary rules, use a simple estheticism, and be creative. To these commandments, they added another one: friendship.

*Nouvelle cuisine* has been described as a blending of Japanese food presentation with French cooking techniques. The concept has taken on a life of its own in the hands of its imitators. In this interpretive study, a tiny piece of meat is served with miniature vegetables (“bonsai” vegetables to food critics), while an upended pastry serves as a vertical element topped with sprigs of blooming thyme. Is it art, or campy novelty?

PHOTO BY ANDRÉ BARANOWSKI.

From then on, *nouvelle cuisine* became quite fashionable. It was everywhere, on television, on the radio, in the newspapers; people talked about it and held controversial discussions. The chefs who had become real stars were rich enough to purchase their own restaurants and become their own masters. The economic boom of the 1960s and the 1970s boosted the careers of the chefs, providing them with much money, which of course incited other less-gifted chefs to follow suit. Unfortunately for several of them, what ought to have been simple, original, or healthy food became approximate, ridiculous, meager food. The journalists who had praised the best chefs, now did the same with drudges, and gave the seal of quality to poor, ridiculous, and botched dishes. As a result, the movement was quite discredited though the greatest chefs were never criticized by those who blamed their imitators. By the 1980s, *nouvelle cuisine* had lost its appeal and today it is no longer used; it even has turned into a pejorative connotation.

The concepts used by the chefs who inspired them predominate within today's grande cuisine, not only in France, but the world over. Products must be selected with a ruthless eye on quality, wines and dishes matched with flair, cooking times short and accurate, and sauces lighter. Judicious blending of foreign trends and customs is a major element. An attractive plate is served, the food displayed simply and esthetically. An open mindedness and a concern for nutrition and diet are the essential ingredients binding the whole approach. Today, there cannot be a grand chef in the world who has not in some way or other been influenced by the nouvelle cuisine ethos.

**NUTRACEUTICALS.** There are many ways to think about food. In the simplest sense, food is fuel. Food provides the energy needed to perform daily functions and maintain normal metabolic processes. But we all know that food is more than fuel. Food contains nutrients that are essential to prevent diseases. For example, scurvy will occur if vitamin C is not continually present in the human diet. Similarly, blindness can occur where diets are deficient in vitamin A. The "essential nutrients"—those that are needed to prevent specific diseases—have been a major focus of human nutrition research for the past century. Through this research we have determined the amount of each essential nutrient required to prevent disease in populations of various ages, cultures, and genetic predispositions. What is interesting, however, is that the link between diet and disease, or more important, diet and health, cannot be entirely explained by the absence or presence of the various essential nutrients in our diets. And so today, a multitude of components that are found in foods are being investigated to determine what, if any, role they play in maintaining health and reducing the risk of disease. Numerous phytochemicals (plant chemicals)

that occur in fruits and vegetables are taking center stage in this research, as more evidence accumulates regarding their health-promoting properties (Beecher, 1999).

#### Human Nutrition Research

Concurrent with these new activities in nutrition research is a reevaluation of the medicinal practices of past and present cultures. These traditional medicines are based largely on the use of plant materials. Chinese medicine, which predates modern medicine by thousands of years, employs a vast array of botanical materials for the treatment of disease and the maintenance of health. Similarly, East Indian Ayurvedic medicine, early European folk medicine, and native North American medicine are based largely on the use of plant materials.

#### Health-Promoting Foods

Today the exploration and exploitation of the disease-fighting properties of a multitude of phytochemicals found in both food and nonfood plants have created a renaissance in human health and nutrition research. At the same time, many opportunities for the development of novel dietary products have been created. With all new fields of study come new terms. "Nutraceuticals" and "functional foods" are two new terms used to describe health-promoting foods or their extracted components. Although debate continues regarding the exact meaning of these terms, it is convenient to consider nutraceuticals as healthful products that are formulated and taken in dosage form (for example, capsules, tinctures, or tablets). Functional foods, on the other hand, are products that are consumed as foods, and not in dosage form.

The beneficial role of many nutraceuticals and functional foods may relate to their protective effects against degenerative diseases, such as cancer and cardiovascular disease. Typically the active ingredient(s) in the food or supplement is believed to help the body combat metabolic processes that lead to degenerative conditions. In this way, supplementing the diet with beneficial phytonutrients may reduce the risk of degenerative diseases

#### NEURODEGENERATIVE PROCESSES

Foods and supplements are also being examined for their effects on neurodegenerative processes. Blueberries have recently been shown to reverse some of the losses in memory and motor skills that occur during aging (Joseph et al., 1999). Ginkgo biloba supplementation may be effective in the prevention and treatment of Alzheimer's disease.

## ANTICANCER AND CARDIOPROTECTIVE PROPERTIES

The anticancer and cardioprotective properties of plant flavonoids and isoflavonoids are being investigated in human health and nutrition research. In the field of biotechnology, genetic techniques are being developed to control the synthesis of flavonoids and isoflavonoids in various food crops (Dixon and Steele, 1999).

during aging. These concepts are well illustrated by the example of dietary antioxidants.

There is overwhelming evidence to suggest that oxygen and its highly reactive by-products are responsible for oxidative damage ("rust") to biomolecules in our bodies. Oxidative damage to biomolecules is believed by many to be a significant factor in the etiology of many degenerative diseases and the aging process itself. Oxidative damage to cellular DNA is an underlying element in the initiation of cancer. Similarly, oxidative damage to low-density lipoprotein in the blood is a causal agent in the development of atherosclerotic plaque in cardiovascular disease. It has been suggested and supported by various types of evidence that consuming antioxidants may provide greater protection against the deleterious effects of oxidative damage (Ames et al., 1993).

Several groups of plant phytochemicals, including carotenoids, tocopherols, and polyphenolics, are extremely effective antioxidants; these antioxidants are found at various levels in fruits, vegetables, and nonfood plants. Thus, with respect to the terms "nutraceutical" and "functional foods," a fresh or processed fruit or vegetable that is particularly high in antioxidant phytochemicals could be considered a functional food. The high antioxidant level may be a normal characteristic of the plant, or may be due to phytochemical fortification during manufacture of a processed food product. A nutraceutical may be an antioxidant phytochemical concentrate, having been extracted from raw materials and formulated as a standardized capsule or tablet (Hasler, 1998).

### Challenges and Opportunities

The field of nutraceuticals and functional foods is new, and many gaps exist in the knowledge base. For example, it is widely accepted that the health-promoting properties of foods are not necessarily due to single components, but rather a few or several active ingredients. This creates a significant paradigm shift from the pharmaceutical model, which is based on the efficacy of

single agents. Many of the bioactive phytochemicals under investigation have long been ignored, thus methods for their handling and measurement are lacking. Manufacturers wish to make specific claims of health benefits on their product labels. Clearly such claims must be based on solid scientific evidence, which to date is often lacking. Government regulatory bodies also face challenges in this new category of health products, which lies between foods and drugs. However, all parties share the desire to improve personal and public health through diet modification, to reap the consequent social and economic benefits.

The field of nutraceuticals and functional foods is at times confused, or at least lumped together with the field of biotechnology and genetic modification. The two areas are distinctly different, although there is some potential for overlap. Techniques in genetic modification may be applied to enhance the phytochemical content of food and nonfood plants. Although the complex series of biochemical reactions used by plants to synthesize specific phytochemicals is often not well understood, there is tremendous potential to harness the plant's sophisticated biochemical machinery to synthesize valuable compounds and ultimately enhance human health.

**NUTRIENT BIOAVAILABILITY.** The chemical analysis of a food gives us values for the total amounts of particular nutrients that are present. Commonly, when a food is to be analyzed, it is first treated with a strong acid,

or an enzyme, that breaks up complex materials into simpler, soluble products. Thus, the starch content of a food may be measured as the amount of additional sugar found after the treatment of the food with an enzyme that acts specifically on starch, and nothing else, to break the large molecules down to glucose. Usually, if different analytical methods are compared, the one giving the highest values is chosen, on the grounds that it has extracted the nutrient in question most completely.

However, from a nutritional point of view our interest is in how much our digestive system will be able to extract in a form that can be absorbed into the bloodstream. The term “digestibility” was formerly used to designate this, but nowadays it is becoming more common to use the term “bioavailability.” It must be remembered that, after a period of preliminary storage and preparatory digestion in the stomach, ingested food passes into the small intestine and it is there that final digestion occurs and the smaller, digestible molecules are absorbed. The residual gut contents are then passed into the large intestine, whose major function is the removal of water, though the presence of a large bacterial population ferments some of the otherwise indigestible components of food. Since the fermented material is not recovered in the feces it may, wrongly, be considered to have been digested, even though it is not “bioavailable.”

The final measure of bioavailability must therefore be some overall response of the subject to a test dose of the food in question. If the subject is a human “guinea pig,” this might be the increased level in the blood of the nutrient in question; if young, growing animals are used, it could be their rate of growth when receiving a supplement of the test food, compared with that of other animals receiving the pure nutrient. We will cite some examples below to illustrate why the subject has some importance, and how it can be studied with different nutrients.

### **Protein**

Proteins are enormous molecules composed of chains of hundreds of amino acids. Our bodies can only build up their own proteins from single amino acids, and the absorptive system of the gut will only allow single amino acids to pass into the bloodstream. This breakdown, which is very efficient for most of the protein in ordinary foods, requires a complex series of enzymes, beginning with pepsin, which is secreted into the stomach. It is only very resistant proteins, like those in hair, that fail to be digested by the combined attacks of digestive enzymes.

In general, cooking makes proteins more digestible by loosening and breaking up some of their natural coatings. However, there is one exception—the so-called Maillard (or Browning) reaction, which occurs when a reducing sugar is heated in contact with protein under conditions of relatively low moisture. These reactions are limited to a subset of amino groups. This reaction is not very common but can occur, for example, if dried skim

milk is used to fortify cookies intended for undernourished toddlers. During the baking the reactive group of the lactose in the dried milk combines with reactive groups on the surface of the protein molecules present. One of these reactive groups is attached to the essential amino acid lysine and the resulting compound is resistant to digestion, so that the protein has lost much of its nutritional value.

### **Niacin**

The disease associated with a deficiency of the vitamin niacin (also called nicotinic acid) is pellagra, which is characterized by terrible dermatitis on parts of the skin exposed to the sun and by mental deterioration. The disease has nearly always been associated with poor people eating a diet based on corn (that is, maize) and little in the way of meat or milk. It is now known that, as the grain matures, the niacin combines with structural materials to form a complex that is not readily broken down by digestive enzymes. This gives the vitamin a very low bioavailability, and ordinary cooking in boiling water does not liberate it. Corn is also lower in the amino acid tryptophan than are other grains (and also lower in tryptophan than meat and milk). By means of a series of chemical reactions in the body, tryptophan can provide an indirect source of niacin.

These two characteristics of corn serve to explain its association with pellagra, which began to be seen in southern Europe when corn first became the staple food of many low-income peasant communities. However, this seemed inconsistent with the fact that pellagra was not a problem among low-income communities in Central America where corn had been the staple food for very long periods. It is now realized that a difference in the way that corn is prepared for cooking in the two geographic areas was at least partly responsible for the differing rates of pellagra. In Central America, corn is traditionally soaked in lime water, which is strongly alkaline, before being cooked and made into tortillas. This treatment, which softens the hard grains, also has the effect of releasing the niacin from its B vitamin complex and making it bioavailable. This is an interesting example of a traditional folk custom having a beneficial effect in addition to the obvious one of softening the grain. It has also been recorded that Native American groups in North America who relied on corn as their staple food, but did not have access to lime, used infusions of wood ash, which is also alkaline, for the same purpose.

Maize came from the New World. One could say, therefore, that the thousands of Europeans who suffered and died from pellagra in the 1800s did so because the first explorers who brought maize to Europe failed to bring with them the cooking instructions that had been adopted from long experience where it had been a staple food for many centuries. Furthermore, people of European origin and habits, but living in the American South, were again subject to the disease in the early 1900s.

## Other Vitamins

Pernicious anemia results from a long-term deficiency of vitamin B<sub>12</sub>. A normal mixed diet provides enough of this vitamin. However, its absorption requires the secretion of a specific “intrinsic factor” by cells in the stomach wall. These cells may atrophy, particularly in some older people, and then the vitamin in the food remains unabsorbed so that, when the tissue reserves are used up, the result is a macrocytic (large cell) anemia and progressive neurological damage. After the problem has been detected, the vitamin can be supplied by intramuscular injection.

Vitamin A is found naturally only in animal products. Many people, for lack of purchasing power or other reasons, eat little or no animal products and meet their need for vitamin A by ingesting carotene and related compounds (carotenoids) that provide the coloring of carrots and are present in all green leafy material. Carotene can be hydrolyzed by enzymes within the gut wall to form active vitamin A. However, it has very limited solubility and can be absorbed only in conjunction with fats. Unfortunately, low-income children in Third World countries who rely on carotenoids as their source of vitamin A also commonly have diets that are very low in fat, so that even a reasonable intake of carotenoids does not save them from blindness and other effects of vitamin deficiency.

## Iron

Deficiency of iron and the resulting anemia is a major nutritional problem in many parts of the world. This metallic element is, of course, an essential component of hemoglobin, the oxygen-carrying chemical in our red blood corpuscles, as well as having other functions. However, iron can also be toxic if the body absorbs much more than it needs, because we have no mechanism for excreting the excess. Our bodies therefore have to regulate the absorption of iron so that very little is absorbed when we already have enough, but that we do absorb more after blood loss, or during pregnancy when the growing fetus has to be provided with its hemoglobin. It appears that there is a feedback system that informs the cells on the inner surface of the small intestine how much iron is required to be absorbed.

However, there are limits to this control, and children may die from acute iron poisoning as a result of finding iron pills and eating them as candy. A small proportion of people also absorb more iron than they need even from a normal diet and suffer from a serious disease (hemochromatosis) as a consequence. Iron, therefore, is a nutrient for which a relative low bioavailability is normal, and in fact essential.

It is estimated that adult men need to absorb about 1 milligram of iron per day to replace their losses from rubbed-off skin, and so forth, and that premenopausal women need to absorb some 50 percent more in order to compensate for losses of menstrual blood. It is commonly recommended that people consume 10 times these

levels each day, on the assumption that there will be about 10 percent bioavailability. In general, “heme iron” from meat is best absorbed, with a typical value of about 20 percent. The absorption of the iron compounds present in vegetable foods is lower and variable, but is increased if vitamin C is present in the same meal. It is particularly low from green vegetables like spinach that are relatively rich in iron but also in another compound called phytic acid or phytate. This compound can form insoluble salts with iron that inhibit its absorption. Legumes (that is, beans, lentils, and peas) are generally richer sources than the grains, but the iron compounds they contain are also less well absorbed than those in meat.

Wheat fully milled to “white flour,” and used to make white bread, is particularly low in iron, and yet it can form a large portion of the diet of many people. Because of this, many technically developed countries legally required that millers add a source of iron, as part of a micronutrient supplement, to all the white flour that they produce. This is a problem for millers because the addition of ferrous sulfate, the common iron salt with relatively high availability, can catalyze the oxidation of fat in foods, producing rancid off-flavors. That can be avoided by adding the actual metal in very fine form. On chemical analysis, this form of iron is fully measured and meets the legislative standard for the iron content of white flour. However, its bioavailability is more doubtful and depends on whether the gastric acid, which it meets in the stomach, is sufficient to react with it to produce soluble salts. Even iron with the finest particle size seems to have only 20 percent of the bioavailability of the iron in ferrous sulfate.

## Other Trace Minerals

Zinc provides the best example of deficiency of a trace mineral occurring in practice as the result of low bioavailability, rather than as a result of an absolute deficiency of the mineral in the diet. In the Middle East, cases were observed of young men who had failed both to grow to normal height and to reach puberty. Tests showed that these subjects did respond to dietary supplements of zinc; even though their diet was low in zinc they were not really deficient in the element. The traditional diet in the area was based on wheat, but it was not customary there when cooking wheat flour to first “raise,” or leaven the dough by fermenting the flour with yeast, as in Western baking. We now realize that yeast, in addition to producing bubbles of carbon dioxide that “raise” the dough, secretes enzymes that hydrolyze the phytate present in the flour. Unfermented products, like “falafel,” still contain a significant amount of phytate and, when they are eaten, the phytate binds with zinc present in the same meal to make it largely unavailable. When a diet includes more meat or fish, which are richer sources of zinc, enough remains uncombined to provide what is required for normal functions; but the young men who had failed to mature and grow were typically from poor families who ate little in the way of animal products.

Another problem with trace minerals is that they share absorption pathways and are, in a sense, in competition with each other. As a consequence, very high intakes of one element can reduce the bioavailability of another. Thus, if one were to take a high supplement of an iron salt, in order to avoid any risk of an iron deficiency, one could precipitate a deficiency of zinc since that element would no longer be so well absorbed. Equally, a particularly high intake of zinc could reduce one's absorption of copper, and so on.

There is no one "ideal diet." Our bodies can tolerate and adapt to considerable differences in the intake of nutrients, but there are limits, and it is clearly dangerous to supplement the diet with a very large amount of a single nutrient. The simplest way to maintain a reasonable balance in one's diet is to follow the traditional advice of eating a wide variety of foods.

**NUTRIENT-DRUG INTERACTIONS.** The terms "nutrient-drug interaction" and "diet-drug interaction" refer to the process whereby the consumption of a food affects the absorption, metabolism, action, retention, and/or excretion of a drug, or conversely the process whereby taking a drug affects the absorption, metabolism, action, retention, and/or excretion of a nutrient.

Adverse consequences of nutrient-drug and diet-drug interactions are so common that in their 1996 accreditation standards, the Joint Commission on Accreditation of Healthcare Organizations began requiring hospitals to ensure that "patients are educated about the potential for drug-food interactions" by "[i]nstruction on potential drug-food interactions and counseling on nutrition intervention and/or modified diets, as appropriate" before they are discharged.

In the following discussion, we will first address the effects of diet and nutritional status on drug absorption, disposition, metabolism, and action; thereafter, we will

address the effects of drugs on nutrient absorption, disposition, metabolism, and action, with attention to certain specific food/nutrient/drug interactions.

#### Terminology Used in Describing Nutrient-Drug Interactions

The following terms are useful when discussing nutrient-drug interactions:

- *Pharmacokinetics*: the characteristics of a drug's absorption, distribution, metabolic transformation (biotransformation), and excretion. Interactions affecting pharmacokinetics are the most common form of nutrient-drug interactions.
- *Pharmacodynamics*: the mechanisms of drug action and the relationships between a drug's concentration at the active site and its pharmacological effects. Interactions affecting pharmacodynamics are less common, and certainly less well-studied, forms of nutrient-drug interaction.
- *Absorption*: the rate at which, and the extent to which, a drug leaves its site of administration. Sites of drug absorption can include all surfaces of the body, and for drugs given by injection, the bloodstream. Specifically, drugs taken orally are absorbed to some extent in the mouth and stomach (if the formulation is designed for this purpose), but predominantly in the small intestine, the organ that is specifically designed for absorption. In order to be absorbed, drug particles must be broken down and dissolved in liquid, for example, by both stomach juices and the fluid you swallow when taking the pill, so that they can reach the cells of their absorption site successfully. Note, however, that there are some drugs that may be destroyed in the stomach—therefore many preparations are coated in order to pass through the stomach intact, and only be broken down when they reach the small intestine.
- *Bioavailability*: the extent to which a drug reaches its site of pharmacological action. In practice, bioavailability is measured as the extent to which the drug reaches the bodily fluid that bathes the tissue site where the drug should act. The bioavailability of a drug increases with increased absorption and distribution of the drug to its site of action, and decreases with increased metabolism and excretion of the drug before it can reach the site of action.
- *Biotransformation*: the process through which drugs, nutrients, and hormones can be metabolized, and thereby either activated or inactivated.

#### Host Factors Affecting the Development of Adverse Interactions between Foods and Drugs

The likelihood of adverse interactions between foods and drugs is affected by the following factors: (1) age, because older people have less metabolic reserve; (2) medical conditions, such as diabetes mellitus, that lead to abnormal-

ities in both food and drug handling; (3) conditions, such as arthritis, that increase the likelihood that the person will be taking over-the-counter medications; (4) sex; (5) size and fat mass, which are related to a person's diet and nutritional status; (6) exclusionary diets, for example, diets from which all animal products are excluded (vegan diets); (7) the use of substances of abuse, such as alcohol, which alter the handling of both drugs and nutrients; and finally, (8) medical conditions that require the care of different specialists and multiple medications.

### Effects of Foods and Food Components on Drug Absorption and Bioavailability

There are at least four ways in which foods and their components can affect the absorption and bioavailability of a drug:

- *Physicochemical binding:* The food component and the drug can bind to each other physicochemically, so that neither the drug nor the component can be absorbed. For example, the antibiotic tetracycline binds with calcium, magnesium, iron, and zinc; once bound, the antibiotic becomes unavailable—that is why this drug should not be taken with dairy products, which contain high amounts of these minerals.
- *Stability:* The food can alter the stability of the drug preparation in the stomach, so that it breaks down before it can be absorbed.
- *Gastric emptying:* The drug or food can change the rate at which the stomach empties, and therefore the rate at which the drug arrives in the small intestine. Gastric emptying is normally a three-phase process. When you begin to eat, a small amount of food mixed with stomach juices enters the small intestine. The presence of this mixture makes the small intestine send a signal to slow down gastric emptying. This slow-down allows the stomach time to thoroughly mix the food with the stomach juices, and to break down the food into small particles. Fatty foods are highly effective in slowing stomach emptying, while erythromycin, an antibiotic, increases the speed of gastric emptying.

A drug taken on an empty stomach is likely to be dumped rapidly into the small intestine. As a result, there will be only one peak in the curve describing the concentration of the drug in the blood across time. By contrast, a drug taken with food will arrive in the small intestine more slowly, and in small spurts (via the second phase of gastric emptying), so that there may be two or more peaks in this curve. Remember, though, that one job of the stomach is to break down pills into particles. If you take a pill on an empty stomach, it may arrive in the small intestine more quickly, but it may not be absorbed if the pill is not sufficiently broken up. Furthermore, a drug taken on an empty stomach will pass more rapidly through the small intestine, with the result that the time for absorption is shorter and less of the drug

may be absorbed. Finally, in the third phase of gastric emptying, approximately every 24 hours, the normal stomach has a massive series of contractions that propel larger particles and any remaining material in the stomach into the small intestine. If there are any large drug particles left behind in the stomach, this “housekeeping” emptying may lead to a sudden dumping of a large quantity of the drug into the small intestine, with a corresponding sharp peak in the blood concentration of the drug. The duration and extent of the phases of gastric emptying in response to food vary considerably from individual to individual, but is longer in women than in men, and is much longer in chronic alcoholics. Smoking while eating also delays stomach emptying.

The fourth way in which foods can affect the absorption and bioavailability of a drug is by:

- *Competition for absorption:* Many drugs use the intestine's natural transport systems—which normally transport food components—to cross the intestinal wall. They therefore compete with food components for transport. For example, L-dopa and methyl dopa (drugs used to control Parkinson's disease) use the same transporter mechanism as aromatic amino acids from proteins, so absorption of these drugs is decreased if you eat a high-protein meal at the same time you take the drug.

In general, we can divide drugs into those that are best absorbed on an empty stomach (for example, most but not all antibiotics, digitalis preparations, captopril, and sucralfate); those absorbed best with food (for example, some hypertension medications such as chlorothiazide and spironolactone, and drugs for blood lipid abnormalities such as lovastatin and gemfibrozil), and those for which absorption varies by the type of preparation or formulation. For example, drugs that are enterically coated (so that they are not destroyed by stomach acid) may be more easily absorbed if they are taken with food, because a long stay in the stomach may weaken the coating just enough that it disintegrates more easily in the small intestine.

The examples given above are general rules and may not be true for the specific preparation you may be taking. Therefore, it is critical to check the package insert for your drug and to consult with your pharmacist. For example, theophylline, a commonly used asthma drug, comes in several different formulations, depending on the manufacturer. One version of theophylline is best absorbed when accompanied by a high-fat meal, while another is poorly absorbed. The rate of absorption of theophylline is extremely important because it is one of the many drugs that has a narrow therapeutic window; in other words, there is a very small difference between the concentration of drug that you need in your bloodstream for it to be effective, and the concentration at which the drug becomes toxic. For the drug to work properly, it is critical to maintain a steady level of the drug in the

bloodstream—neither too little nor too much. Therefore, switching from one formulation to another has to be done carefully.

### Effects of Foods and Food Components on Drug Biotransformation

Biotransformation can be divided into two phases: Phase I, in which compounds are transformed by enzymes (proteins that transform the structure of other molecules such as drugs to make them either inactive or more active), and Phase II, in which compounds are prepared for excretion in the urine by attaching a molecule that makes them soluble in water. The small intestine has some capacity for drug biotransformation, but the major site of biotransformation is the liver. Because blood from the small intestine must pass through the liver before it goes on to the rest of the body, some drugs that are readily absorbed may not be bioavailable, because they are inactivated by the liver before they can get to the site of action. Blood flow through the liver, and the size of the liver itself, decrease as people age, so some drugs may be effective at lower doses in the elderly than in the young.

The dietary factors that activate the liver enzymes are just beginning to be elucidated. These include both nutritive factors (protein, carbohydrate, and fat) and non-nutritive factors, compounds in charbroiled meat, in cruciferous vegetables such as cabbage, turnip, and broccoli, and in citrus fruits, especially grapefruit. If you are taking a drug that is activated or inactivated by liver enzymes, it is important to maintain a diet that does not vary much from day to day in order to assure a steady level of the active drug in your bloodstream. Note that large changes in macronutrient composition of your diet, for example, adoption of a low-protein diet, can also affect Phase II biotransformation, and therefore drug excretion.

### Effects of Drugs on Food and Nutrient Intake and Function

Drugs can affect food and nutrient intake, either as a desired effect or as a side effect. They can alter appetite; cause nausea and vomiting; cause food aversions; alter the taste of food, decrease taste sensations, or cause the mouth to be painful; cause gastric irritation; and alter intestinal function. One class of drugs that can cause all of these problems consists of the anticancer drugs, which can potentially cause malnutrition because they can decrease food intake dramatically.

### Specific Diet/Food-Drug Interactions

There is a large number of well-known food-drug interactions in which the drug's action is altered by specific dietary components. Common examples are diuretics used for hypertension, digoxin used for cardiovascular disease, coumarin anticoagulants used for blood thinning, and monoamine oxidase (MAO) inhibitors used for depression. Similarly, there are a number of drugs, such as

the drugs designed to reduce stomach acidity, that affect vitamin and mineral status, requirements, and activity.

Drugs can inhibit enzymes that may be critical for the metabolism of toxic substances in food. In the case of disulfiram, a drug used to curb alcohol consumption, the enzyme inhibition is the desired therapeutic effect. This drug inhibits aldehyde dehydrogenase, the enzyme that breaks down the aldehyde derived from alcohol consumption. As a result, people taking the drug become ill when they drink alcohol, and thus learn to avoid alcohol. For most drugs, however, food-drug incompatibility is an undesirable side effect.

### General Principles

The considerations we have discussed bring us to enunciate two important general principles:

1. First, if you are taking any drug, either prescription or over-the-counter, be sure to consult your pharmacist concerning any nutrient-drug interaction for that drug.
2. Second, be sure to take both drug and food on a regular basis, so that drug absorption, action, metabolism, and excretion are consistent and predictable.

**NUTRIENTS.** Nutrients are those organic and inorganic compounds that a living organism must acquire from the environment to support essential life processes, including basal metabolism, growth and maintenance of body tissues, activity, reproduction, and maintenance of general health. Nutrients are normally obtained by the ingestion of foods. Organic nutrients include carbohydrates, proteins or amino acids, lipids, and vitamins. Inorganic nutrients include minerals. Water is sometimes included in a listing of nutrients.

### Classification of Nutrients

Nutrients often are classified as essential or nonessential. Essential nutrients are those that cannot be synthesized in the body at all or in sufficient amounts to meet needs and, thus, must be obtained preformed in the diet. These include the essential (indispensable) amino acids, the es-

sential fatty acids, the vitamins, and the minerals. Two amino acids are classified as semi-essential because, although they can be synthesized in sufficient quantities in the body, their synthesis depends upon a supply of an essential amino acid. Other nutrients are considered conditionally essential, meaning that they are not normally required by a healthy adult but may be required in certain disease states or at certain stages of life because of increased demand or impaired synthesis. Nonessential nutrients include those that are oxidized as fuels and those that provide carbon skeletons and amino groups for endogenous synthesis of body constituents. The term “dispensable” is sometimes used to describe these nutrients, as the nutrients are not truly nonessential: an adequate amount of carbohydrate, protein, and fat must be taken in to supply the substrates required for maintenance of blood glucose, as fuel for oxidative metabolism and synthesis of ATP, and as substrate for synthesis of body components. They are “nonessential” only in the sense that carbohydrate, fat, or protein, as well as ethanol, can be used as fuels; in that either carbohydrate or protein or even the glycerol backbone of triacylglycerols (fat) can be a source of glucose; in that any fuel potentially can be used for synthesis of most lipids; and in that amino groups from most amino acids can be used for synthesis of indispensable amino acids. Also, some food components that have health benefits and are considered important parts of healthy diets, such as fiber and phytochemicals, are not required and are not considered nutrients per se.

The following table summarizes the nutrient classes, the essential compounds in each class, and the basic functions of these nutrients in the body.

Additional information about some of these nutrients can be found below. Additional information for the other nutrients can be found under separate entries in this volume.

### Niacin

The term “niacin” is used to refer to either nicotinic acid (pyridine-3-carboxylic acid) or nicotinamide (pyridine-3-carboxamide). Niacin is widely distributed in foods of both plant and animal origin. Good sources of niacin include meats, poultry, fish, legumes, peanuts, some cereals (mainly in the bran), and enriched or whole grain products. Much of the niacin in cereals is not readily available because it is esterified to complex carbohydrates or peptides.

The amino acid tryptophan also is an important precursor for synthesis of pyridine nucleotide coenzymes (see below). The estimated conversion factor for adults is 60 mg of tryptophan to 1 mg of niacin. The term “niacin equivalent” (NE) is used for expression of niacin intakes and requirements, with either 1 mg of nicotinic acid, 1 mg of nicotinamide, or 60 mg of tryptophan equal to 1 NE.

The adult recommended daily (or dietary) allowance (RDA) for NEs is 14 mg per day for females and 16 mg

per day for males (Institute of Medicine, 1998). Most mixed diets in the United States provide more than 5 mg of preformed niacin. However, for individuals consuming typical Western diets, most NEs are derived from tryptophan rather than from preformed niacin. The tryptophan content of proteins ranges from about 0.6 percent for corn to 1.5 percent for animal products. Assuming that the average tryptophan content of protein is about 1 percent, a diet for adults that contains 100 g or more of protein provides about 16 mg NEs and would by itself meet the RDA for niacin. One should note that food composition tables do not take into account the bioavailability of niacin (from plant foods) and do not include an estimate of the NE available from tryptophan in the food. The adult male RDA for NEs would be supplied by  $\frac{1}{4}$  cup peanut butter,  $3\frac{1}{2}$  slices roast beef,  $4\frac{1}{2}$  cups green peas, or 15 slices enriched wheat bread.

Nicotinic acid and nicotinamide are actively absorbed from the small intestine as well as from the renal filtrate. Niacin metabolites are excreted in the urine. Defects in tryptophan absorption or reabsorption from the renal filtrate have been associated with cases of niacin deficiency (pellagra).

Niacin is essential for the formation of the pyridine nucleotide coenzymes, nicotinamide adenine dinucleotide (NAD), and nicotinamide adenine dinucleotide phosphate (NADP). Reduced forms of these coenzymes are indicated as NADH and NADPH. NAD and NADP function in oxidation-reduction reactions that are involved in the catabolism of glucose, fatty acids, ketone bodies, and amino acids. These coenzymes ultimately funnel electrons to electron-to-oxygen transfer systems, including the mitochondrial electron transport chain. These coenzymes also are essential for reductive biosynthetic reactions. In addition, NAD has a non-coenzyme function: NAD serves as the donor of adenosine diphosphate-ribose moieties for ADP-ribosylation reactions. Poly-ADP-ribosylated proteins appear to function in DNA repair, DNA replication, and cell differentiation.

Symptoms of pellagra, or niacin deficiency, include functional changes in the gastrointestinal tract and nonspecific lesions of the central nervous system. Early symptoms include weakness, lassitude, anorexia, and indigestion. Later symptoms include various gastrointestinal and mental symptoms and a bilaterally symmetrical dermatitis that affects parts of the body exposed to sunlight, heat, or mild trauma. Pharmaceutical doses of nicotinic acid cause vasodilation, and long-term use can cause gastrointestinal irritation and possibly liver damage. The tolerable upper intake level (UL) set by the Institute of Medicine (1997) is 35 mg of niacin per day for adults.

### Riboflavin

Riboflavin is the common name for 7,8-dimethyl-10-(1'-D-ribityl)isoalloxazine, which also is known as vitamin B<sub>2</sub>. Much of the riboflavin in the American diet is supplied by dairy products. Meats, especially organ meats,

TABLE 1

Summary of nutrients and their functions		(See Appendix for complete chart of vitamins.)
Nutrient class	Essential compounds in class	Function in body
<b>Carbohydrates</b> (composed of glucose, galactose, fructose, and other sugars)	None	Fuel—oxidation or storage as glycogen; Source of carbon skeletons for synthesis of various organic compounds
<b>Proteins</b> (composed of amino acids)	Histidine Isoleucine Leucine Lysine Methionine (and Cysteine) Phenylalanine (and Tyrosine) Threonine Tryptophan Valine  Sufficient total amino acids to supply amino groups for synthesis of nonessential amino acids	Protein synthesis; Substrate for synthesis of essential nonprotein compounds; Source of amino groups for synthesis of nonessential amino acids; Source of carbon skeletons for synthesis of various organic compounds including glucose and nonessential amino acids; Fuel—oxidation or conversion to carbohydrate or fat for storage
<b>Lipids</b>	n-6 Essential fatty acids (e.g., linoleic acid) n-3 Essential fatty acids (e.g., $\alpha$ -linolenic acid)  Sufficient dietary lipids to ensure adequate absorption of fat-soluble vitamins	Fuel—oxidation or storage; Carbon skeletons for synthesis of various organic compounds in body; Polyunsaturated (n-6 and n-3) fatty acids are required for synthesis of eicosanoids, inositol phosphoglycerides, sphingolipids, and membrane phospholipids
<b>Vitamins</b> B vitamins	Niacin  Thiamin  Riboflavin  Vitamin B <sub>12</sub>  Folate  Vitamin B <sub>6</sub>  Pantothenic Acid	Synthesis of coenzymes NAD(H) and NADP(H) that participate in oxidation-reduction reactions; Substrate for ADP-ribosylation of macromolecules  Synthesis of coenzyme thiamin pyrophosphate (TPP) that is required by transketolase and $\alpha$ -ketoacid dehydrogenase complexes  Synthesis of coenzymes FAD and FMN that participate in oxidation-reduction reactions  Synthesis of coenzymes deoxyadenosylcobalamin and methylcobalamin that participate in the metabolism of methionine and of propionyl/methylmalonyl CoA, respectively  Synthesis of folate coenzymes, including tetrahydrofolate, methyl-tetrahydrofolate, methylene-tetrahydrofolate, and 10-formyl-tetrahydrofolate; the coenzymes are required for the metabolism of glycine, serine, methionine, and histidine, and the synthesis of purines and dTMP  Synthesis of coenzymes pyridoxal 5'-phosphate (PLP) and pyridoximine 5'-phosphate (PMP) that are involved in amino acid metabolism  Synthesis of coenzyme A; Synthesis of acyl carrier protein domain of fatty acid synthase
Other Vitamins	Biotin  Vitamin C  Vitamin A  Vitamin D Vitamin E Vitamin K	Coenzyme for synthesis of holocarboxylases  Electron donor for enzymatic and nonenzymatic reactions  Precursor of 11- <i>cis</i> -retinal required for visual function; Precursor of all- <i>trans</i> retinoic acid and other metabolites that bind retinoid nuclear receptors  Precursor of vitamin D hormone Lipid-soluble antioxidant Substrate for $\gamma$ -glutamylcarboxylase
[continued]		

TABLE 1 (CONTINUED)

Summary of nutrients and their functions		
Nutrient class	Essential compounds in class	Function in body
Minerals		
	Macroelements	
	Calcium	Regulation of cellular activities by intracellular $\text{Ca}^{2+}$ ( $2^{\text{d}}$ messenger function); Activation of certain proteins; Effects on excitability of nerve and muscle tissues; Component of mineralized tissue
	Phosphorus	Substrate for synthesis of nucleotides, DNA and RNA, phospholipids, signaling molecules, creatine phosphate, and other phosphoesters; Regulation of protein function via phosphorylation of tyrosyl, seryl, or threonyl residues of proteins; Substrate for oxidative phosphorylation (ATP synthesis); Component of mineralized tissue; Acid-base buffer system
	Magnesium	Anion charge neutralization (e.g., $\text{Mg}^{2+}\text{ATP}^{4-}$ ); Essential for function of certain proteins; Stabilization of DNA and RNA structures
	Sodium	Membrane potentials of all cells and excitability of nerve and muscle tissues; Major extracellular cation; Generation and maintenance of electrical and osmotic gradients; Nutrient transport
	Potassium	Major intracellular cation; Membrane potential and excitability of nerve and muscle tissues
	Chloride (Sulfur)	Major inorganic anion in body fluids Not essential as sulfur because sufficient inorganic sulfur is formed from catabolism of methionine and cysteine; Synthesis of Fe-S cluster proteins, various sulfoesters, including those in glycosaminoglycans
Microelements	Iron	Synthesis of heme proteins, iron-sulfur cluster proteins, Fe-containing metalloenzymes
	Zinc	Conformation of zinc-finger proteins; Metalloenzymes—catalytic and noncatalytic roles
	Copper	Metalloenzymes—catalytic role
	Manganese	Metalloenzymes—catalytic and regulatory roles
	Iodine	Synthesis of thyroid hormone
	Molybdenum	Synthesis of Mo-containing coenzyme
	Selenium	Synthesis of selenocysteinyl residues of selenoproteins
	Boron and Chromium?	Probably are essential
	Nickel, Vanadium, Silicon, Arsenic, and Fluorine?	Possibly are essential (Although fluorine is not known to be nutritionally essential, its health benefits in prevention of dental caries are significant and fluoride intake, mainly from water, is recommended.)
	(Cobalt)	Vitamin $\text{B}_{12}$ contains cobalt, but inorganic cobalt is not required

eggs, and vegetables such as broccoli, spinach, and mushrooms are also good sources. Enriched flour and enriched breakfast cereals also contribute significantly to riboflavin intakes. The RDA for riboflavin is 1.3 mg for men and 1.1 mg for women (Institute of Medicine, 1998). Some amounts of common foods that would need to be con-

sumed to supply 1.3 mg of riboflavin (assuming they were the sole dietary source of this vitamin) are 3 cups milk,  $1\frac{1}{4}$  pounds beef round, 8 large eggs,  $4\frac{1}{3}$  cups broccoli, or 65 slices whole wheat bread. Daily intakes of riboflavin in the United States average about 1.5 to 2 mg for adults (Institute of Medicine, 1998).

Following ingestion, flavin coenzymes are released from noncovalent attachment to proteins by gastric acidification and subsequent proteolysis. Nonspecific pyrophosphatases and phosphatases act on coenzyme forms to release riboflavin. Covalently bound flavin coenzymes make up about 5 percent to 10 percent of the riboflavin naturally occurring in foods, and the 8 $\alpha$ -(amino acid)-riboflavins obtained from their digestion cannot be used for resynthesis of coenzymes. Free riboflavin is actively taken up from the small intestine. Riboflavin and small amounts of riboflavin catabolites are excreted in urine.

Riboflavin is required for synthesis of flavin mononucleotide (FMN), which is riboflavin 5'-phosphate, and flavin-adenine dinucleotide (FAD). Fully reduced forms of these coenzymes are indicated by FMNH<sub>2</sub> and FADH<sub>2</sub>. Riboflavin coenzymes are involved in oxidation-reduction reactions in which the ring portion of the coenzyme undergoes sequential addition or loss of hydrogens and electrons. Flavoproteins function in either one- or two-electron transfer reactions.

The flavin coenzymes, FAD and FMN, function indispensably in oxidation-reduction reactions involved in the catabolism of glucose, fatty acids, ketone bodies, and amino acids, as well as in energy production via the respiratory chain and in reductive biosynthetic reactions.

Inadequate dietary intake of riboflavin can result in stunting of growth, a variety of lesions involving the skin and the epithelium of the gastrointestinal tract, anemia, and neuropathy. Riboflavin has a low toxicity, perhaps because of its low solubility or ready excretion in the urine. No tolerable upper intake level has been established because of a lack of suitable data.

### Thiamin

Thiamin, also known as vitamin B<sub>1</sub>, is 3-(2-methyl-4-aminopyrimidinyl)methyl-4-methyl-5-( $\beta$ -hydroxyethyl)thiazole. Excellent sources of thiamin include unrefined cereal germs and whole grains, meats (especially pork), nuts, and legumes. Enriched flours and grain products in the United States contain thiamin, as well as niacin, riboflavin, iron, and folic acid.

The RDAs for thiamin are 1.2 mg of thiamin for men and 1.1 mg for women (Institute of Medicine, 1998). Typical intakes of thiamin in the United States average 1.2 to 2.0 mg per day for adults (Institute of Medicine, 1998). The recommended 1.2 mg of thiamin per day is provided by a 3½-ounce pork chop, 20 slices of whole wheat bread, 1⅔ cups of pecan halves, or 17 ounces of roasted peanuts.

Thiamin is released from its phosphate ester forms in which it is found in most natural foods by the action of pyrophosphatases and phosphatases in the small intestine. Free thiamin is absorbed by an active transport process that is probably carrier mediated. Trapping of thiamin as thiamin pyrophosphate in the mucosal cells appears to facilitate the uptake by metabolic trapping. Excess thiamin is excreted in the urine as various metabolites.

Raw fish may contain microbial thiaminases, which hydrolyze and, thus, destroy thiamin in the gastrointestinal tract. Certain thiamin antagonists that are found in coffee, tea, rice bran, and heme-containing animal products can impair thiamin uptake or utilization. Chronic alcoholism results in impaired thiamin absorption, which may be secondary to a folate deficiency. Thiamin requirements also appear to be elevated in individuals with high caloric intakes, especially when calories are derived primarily from carbohydrates, in renal patients undergoing long-term dialysis, in patients fed intravenously for long periods, and in patients with chronic febrile infections.

Thiamin is required for synthesis of thiamin pyrophosphate (TPP), which is also known as thiamin diphosphate (TDP); this may be the sole coenzyme form of thiamin. However, monophosphate and triphosphate esters occur naturally, and thiamin triphosphate has been implicated in nerve function. TPP functions in two general types of reactions in which TPP functions as a Mg<sup>2+</sup>-coordinated coenzyme for "active aldehyde transfers." First, TPP is a coenzyme for the oxidative decarboxylation of  $\alpha$ -keto acids (catalyzed by the pyruvate,  $\alpha$ -ketoglutarate, and branched-chain keto acid dehydrogenase complexes). Second, TPP is required as a coenzyme for transketolase, which catalyzes sugar rearrangements in the pentose phosphate pathway of glucose metabolism.

Thiamin deficiency, or beriberi, affects the nervous and cardiovascular systems. Clinical symptoms include mental confusion, anorexia, muscular weakness, ataxia, peripheral paralysis, paralysis of the motor nerves of the eye, edema, muscle wasting, tachycardia, and an enlarged heart. In Western countries, symptomatic thiamin deficiency is usually observed only in association with alcoholism.

No toxic effects of thiamin administered by mouth have been reported in humans, and thiamin is readily cleared by the kidneys. Injection of doses of thiamin that are more than 200 times those required for optimal nutrition produces a variety of pharmacological effects and can even induce death because of depression of the respiratory center. No tolerable upper intake level has been established for thiamin because of a lack of sufficient data.

### Vitamin B<sub>12</sub>

Vitamin B<sub>12</sub>, or cobalamin, consists of a central cobalt atom coordinately linked to the four pyrrole nitrogens of a heme-like planar corrin ring structure. The 5<sup>th</sup> coordinate bond of cobalt is to one of the nitrogens in a phosphoribo-5,6-dimethylbenzimidazolyl side group of the corrin ring structure, and the 6<sup>th</sup> coordinate bond of cobalt can be occupied by a number of ligands. In vitamin B<sub>12</sub> preparations, this ligand is typically a cyano group that is formed by trace amounts of cyanide during purification of the vitamin from natural sources.

Vitamin B<sub>12</sub> is synthesized by some anaerobic microorganisms and by some algae, such as seaweed. Most

plants and higher organisms do not use vitamin B<sub>12</sub> as a coenzyme, and they do not synthesize it. Vitamin B<sub>12</sub> is found in meat, dairy products, some seafoods, and in fortified cereals. A strictly vegetarian diet contains low levels of vitamin B<sub>12</sub>, most of which come from algal sources or possibly microbial contamination associated with plant roots.

The RDA for vitamin B<sub>12</sub> is 2.4 micrograms for adults (Institute of Medicine, 1998). This amount of vitamin B<sub>12</sub> can be obtained from 1/10 ounce of beef liver, 1 egg, or 2 2/3 ounces of canned tuna. Typical intake of vitamin B<sub>12</sub> in the United States averages 3.3 to 5.6 micrograms per day for adults (Institute of Medicine, 1998).

Absorption of vitamin B<sub>12</sub> is a complex process. Vitamin B<sub>12</sub> in food must be released from proteins to which it is naturally bound; this is accomplished in the stomach by the acid environment and by proteolysis of proteins by pepsin. The vitamin B<sub>12</sub> then binds to other proteins that have affinity for vitamin B<sub>12</sub>, but these binding proteins are hydrolyzed by pancreatic proteases in the small intestine. The free vitamin B<sub>12</sub> then binds to an intrinsic factor, which is a high-affinity vitamin B<sub>12</sub>-binding protein secreted by the gastric glands. The vitamin B<sub>12</sub>-intrinsic factor complex binds to receptors located near the end of the small intestine, and the complex is taken up by endocytosis. The intrinsic factor is degraded by lysosomal enzymes, and free vitamin B<sub>12</sub> is released into the cytosol of the mucosal cells. The vitamin B<sub>12</sub> is released from the intestinal mucosal cells into the plasma as a complex with another protein, transcobalamin II. The transcobalamin II-B<sub>12</sub> complex is transported into tissues by receptor-mediated endocytosis; the complex is degraded in the lysosome, and the free vitamin B<sub>12</sub> is transported out of the lysosome into the cytosol.

Vitamin B<sub>12</sub> is excreted from the body in the urine. It is also secreted in the bile, but vitamin B<sub>12</sub> secreted in the bile is normally reabsorbed via the enterohepatic circulation. Vitamin B<sub>12</sub> is needed for synthesis of two coenzymes: methylcobalamin, which is a cofactor for cytosolic methionine synthase, and 5'-deoxyadenosylcobalamin, which is a cofactor for mitochondrial methylmalonyl CoA mutase.

Vitamin B<sub>12</sub> deficiency seldom is caused by a dietary lack of the vitamin and most commonly is because of a defect in vitamin B<sub>12</sub> absorption. Malabsorption of vitamin B<sub>12</sub> can result from a lack of intrinsic factor secretion, decreased gastric acid production, or pancreatic enzyme insufficiency. Food vitamin B<sub>12</sub> is malabsorbed by many elderly individuals, and it is recommended that adults older than 50 years ingest adequate vitamin B<sub>12</sub> from supplements or fortified foods. Symptoms of vitamin B<sub>12</sub> deficiency include megaloblastic anemia and a severe, and often irreversible, neurological disease called subacute combined degeneration.

No toxicity of vitamin B<sub>12</sub> has been reported. Absorption is limited by the amount of intrinsic factor

secreted. No tolerable upper intake level has been established for vitamin B<sub>12</sub> because of lack of suitable data.

### Vitamin B<sub>6</sub>

Vitamin B<sub>6</sub> refers to several 4-substituted 2-methyl-3-hydroxyl-5-hydroxymethylpyridine compounds, which include pyridoxal, pyridoxine, pyridoxamine, and their respective 5'-phosphate derivatives. Good sources of vitamin B<sub>6</sub> include cereals, meat, especially organ meats, poultry, fish, starchy vegetables, and noncitrus fruits and juices.

The RDA for vitamin B<sub>6</sub> is 1.3 mg for adults (Institute of Medicine, 1998). The median intake of vitamin B<sub>6</sub> from food sources (i.e., not including supplements) is about 2 mg for men and about 1.5 mg for women. Amounts of some foods that would by themselves supply the daily RDA for vitamin B<sub>6</sub> include 1 1/3 whole chicken breasts, 2 bananas, 1 1/3 cups of oatmeal, 12 cups of milk, or 22 large eggs.

Phosphate derivatives of vitamin B<sub>6</sub> are hydrolyzed by phosphatase prior to uptake from the small intestine. Some plants contain pyridoxine as a glucoside derivative; these normally are deconjugated by a mucosal glucosidase before the pyridoxine is absorbed. Vitamin B<sub>6</sub> in a mixed diet is about 75 percent bioavailable, whereas the vitamin B<sub>6</sub> in supplements is about 90 percent bioavailable. Vitamin B<sub>6</sub> is absorbed by a nonsaturable passive diffusion mechanism with metabolic trapping of the vitamers by formation of the phosphate derivatives. Excess vitamin B<sub>6</sub> is excreted in the urine. The major excretory form of vitamin B<sub>6</sub> is the 4-carboxylate derivative 4-pyridoxic acid, but unmetabolized vitamin also is excreted and may be the major excretory form when very high doses of vitamin B<sub>6</sub> are ingested.

Vitamin B<sub>6</sub> is used to form pyridoxal phosphate (PLP), this vitamin's major coenzyme form. PLP binds to proteins and PLP-dependent enzymes via Schiff base formation with the ε-amino group of specific lysyl residues in the proteins. PLP serves as a coenzyme for many enzymes involved in amino acid metabolism, including aminotransferases, decarboxylases, aldolases, racemases, and dehydratases. Aminotransferase reactions convert the coenzyme between the PLP and pyridoxamine phosphate forms.

Vitamin B<sub>6</sub> deficiency can result in seborrheic dermatitis, microcytic anemia (because of decreased hemoglobin synthesis), convulsions, depression, and confusion. Low vitamin B<sub>6</sub>, folate, or vitamin B<sub>12</sub> intakes can lead to an elevated plasma homocysteine level. Alcoholics tend to have low vitamin B<sub>6</sub> status.

Some subjects taking very large pharmaceutical doses of pyridoxine have developed severe sensory neuropathy. There is some evidence for toxicity at daily doses of 500 mg or more, and a safe upper level of intake is thought to be 100 mg/day. The tolerable upper intake level set for vitamin B<sub>6</sub> by the Institute of Medicine (1998) is 100 mg/day for adults.

## Pantothenic Acid

Pantothenic acid, also known as vitamin B<sub>5</sub>, consists of a  $\beta$ -alanine moiety condensed with pantoic acid. Pantothenic acid is distributed widely in plant and animal sources. Meat (especially liver), fish, poultry, milk, yogurt, legumes, and whole-grain cereals are good sources of pantothenic acid. Pantothenic acid is present in foods in the free form and in various bound forms, including coenzyme A, coenzyme A esters, acyl carrier protein, and glucosides.

The Adequate Intake established for pantothenic acid by the Institute of Medicine (1998) is 5 mg per day for adults. This amount of pantothenic acid can be obtained by eating 2½ cups of peanuts, 6 eggs, 3 whole chicken breasts, 6½ cups of milk, or 19 slices of whole wheat bread. The average dietary intake of pantothenic acid in the United States is about 5 to 6 mg, with somewhat lower average intakes in the elderly and young children.

Dietary coenzyme A, coenzyme A esters, and acyl carrier protein are degraded enzymatically in the small intestine to release free pantothenic acid. Pantothenic acid is taken up by active transport. Approximately 50 percent of dietary pantothenic acid is available. Pantothenic acid is excreted unchanged in the urine. The kidneys regulate excretion of pantothenic acid, secreting it when plasma concentrations are high and largely reabsorbing it when plasma concentrations are in the physiological range.

Cells use pantothenic acid to synthesize coenzyme A, which consists of pantothenate linked to cysteamine by a peptide bond and to a 3'-phospho-ADP moiety via a phosphoester linkage. Coenzyme A contains a reactive sulfhydryl group that is involved in the formation of thioesters with fatty acids and other carboxylic acids. Coenzyme A plays a major role in fatty acid metabolism and in the final oxidative steps in the catabolism of all fuels. Much of the metabolism of fatty acids and certain amino acid derivatives, as well as a numerous amphibolic steps in metabolism, use coenzyme A thioester substrates and produce coenzyme A thioester products. Coenzyme A also is used for the synthesis of the acyl carrier protein domain of fatty acid synthase, a multifunctional enzyme that catalyzes palmitate synthesis. Coenzyme A is involved in oxidative decarboxylation reactions catalyzed by  $\alpha$ -keto acid dehydrogenase complexes,  $\beta$ -oxidation of fatty acids, ketone body synthesis, fatty acid and triacylglycerol synthesis, amino acid and organic acid catabolism, and in synthesis of isoprenoids, cholesterol, and steroids.

A naturally occurring deficiency of pantothenic acid has not been documented reliably and is undoubtedly rare because of the wide distribution of pantothenic acid in foods. Pantothenic acid deficiency has been produced experimentally in a small number of volunteers via a pantothenic acid-free diet; these volunteers appeared listless and complained of fatigue after nine weeks on the pan-

tothenic acid-free diet. A "burning feet" syndrome that was observed among prisoners of war and among malnourished individuals in Asia may have been because of pantothenic acid deficiency, as symptoms appeared to be reduced by pantothenic acid.

Pantothenic acid is relatively nontoxic. Doses below 10 g of pantothenic acid per day do not seem to be associated with any toxic symptoms. No tolerable upper intake limit was set by the Institute of Medicine (1998) because of insufficient data.

## Biotin

Biotin contains a ureido group attached to a tetrahydrothiophene ring and has a valeric acid side chain extending from the tetrahydrothiophene ring. Biotin is synthesized by bacteria, yeast, algae, and some plant species. Biotin is distributed widely in foods, existing both as free biotin and as biotin covalently bound to lysyl residues in biotinyl-proteins. Liver, whole-grain cereals, nuts, legumes, yeast, and egg yolks are relatively high in biotin. Biotin is synthesized by microflora in the large intestine, but biotin produced at that site appears to be excreted mainly in the feces.

The Adequate Intake for biotin, as set by the Institute of Medicine (1998), is 30 micrograms per day for adults. About 3 ounces roasted peanuts, 3 medium eggs, 5 cups of milk, ½ cup of peanut butter, or 1½ cups of oatmeal will provide 30 micrograms of biotin. The daily intake of biotin in Western countries is estimated to be about 60 micrograms per day.

Digestion of proteins releases biotinyl-lysine (biocytin) and small lysine-containing peptides with biotin attached covalently. These are hydrolyzed to release free biotin by a specific hydrolase called biotinidase that is present in the pancreatic digestive secretions. Free biotin is transported into the mucosal cells of the small intestine by a carrier-mediated, sodium-dependent process.

Biotin is excreted as such and as several degradation products. Degradation products include bisnorbiotin, in which the 5-carbon valerate side chain has been shortened by two carbons, and biotin sulfoxide, in which the thiophene ring sulfur has been oxidized to a sulfoxide.

The only known function of biotin in humans and other mammals is as a prosthetic group for four carboxylases: pyruvate carboxylase, acetyl CoA carboxylase, propionyl CoA carboxylase, and 3-methylcrotonyl CoA carboxylase (in the pathway of leucine catabolism). Holo-carboxylase synthetase attaches biotin to the apocarboxylases in an ATP-requiring reaction; the biotin is attached by an amide bond to an  $\epsilon$ -amino group of a specific lysyl residue in the enzyme protein. In the holocarboxylases, biotin serves as a CO<sub>2</sub> carrier and carboxyl donor to substrates.

A dietary deficiency of biotin is very rare because of the wide distribution of biotin in foods. Biotin deficiency with clinical symptoms of hair loss, dermatitis, and neu-

rological symptoms has occurred in individuals consuming an abnormal diet that is low in biotin and high in raw egg white. Raw egg white contains avidin, a protein that binds biotin with a very high affinity and prevents its uptake from the intestine. Biotin deficiency may occur in individuals who routinely take certain anticonvulsants or in individuals with severe protein-energy malnutrition. 3-Hydroxyisovalerate is elevated in the urine of biotin-deficient subjects.

Intakes of biotin up to 10 mg per day have not been reported to be associated with toxicity. No tolerable upper intake level has been set for biotin because of lack of data. Inborn errors of biotin metabolism, biotinidase deficiency and holocarboxylase synthetase deficiency, can both be treated with pharmacological doses of biotin.

### Vitamin C

Ascorbic acid or vitamin C is a 6-carbon lactone synthesized from glucose by plants and many animals. Humans, as well as nonhuman primates and several other species, are unable to synthesize ascorbic acid because of a lack of gulonolactone oxidase, the terminal enzyme in the biosynthetic pathway.

Ascorbic acid is found in many fruits and vegetables. Some dietary vitamin C is present as an oxidized form, dehydroascorbic acid. Cantaloupe, kiwi, oranges, lemons, strawberries, and watermelon are especially high in vitamin C. Vegetables that are rich sources of vitamin C include broccoli, red peppers, cauliflower, brussels sprouts, asparagus, potatoes, cabbage, spinach, collard greens, green peas, and carrots. Citrus juices and tomato juice are good sources of vitamin C. Many foods, such as fruit drinks and breakfast cereals, are fortified with vitamin C.

The current RDA for vitamin C is 75 mg for women and 90 mg for men (Institute of Medicine, 2000). An additional 35 mg per day is recommended for smokers. The adult female RDA is contained in  $\frac{3}{4}$  cup orange juice, 1 orange, 1 kiwi,  $\frac{1}{3}$  cantaloupe, 1 small sweet pepper, 2 cups broccoli, or 3 baked potatoes. Typical intake of vitamin C by adults is 70 to 100 micrograms per day.

Ascorbic acid absorption probably occurs by a Na<sup>+</sup>-dependent system in the intestine. Bioavailability is close to 100 percent for vitamin C at doses between 15 and 200 mg but declines at higher doses. Ascorbic acid and its metabolites are excreted mainly in the urine.

Ascorbic acid acts as an electron donor, or reducing agent. Two electrons are lost, probably sequentially, with formation of semidehydroascorbic acid (free radical) and dehydroascorbic acid. Dehydroascorbic acid can be enzymatically or nonenzymatically reduced back to ascorbate or hydrolyzed irreversibly to 2,3-diketogulonic acid, which is converted to other products, including oxalate.

Vitamin C acts as an electron donor for eight mammalian enzymes: three dioxygenases that are involved in collagen hydroxylation (prolyl 4-hydroxylase, prolyl 3-hydroxylase, and lysyl hydroxylase), two dioxygenases

that are involved in carnitine synthesis (6-N-trimethyl-L-lysine hydroxylase and  $\gamma$ -butyrobetaine hydroxylase), 4-hydroxyphenylpyruvate dioxygenase, dopamine  $\beta$ -hydroxylase, and peptidylglycine  $\alpha$ -amidating monooxygenase. Ascorbic acid may also function in nonenzymatic reduction reactions and thus acts as a water-soluble antioxidant.

An early sign of vitamin C deficiency is fatigue. With more severe deficiency, petechial hemorrhage, coiled hairs, ecchymoses, bleeding and tenderness of the gums, hyperkeratosis, joint pain, and shortness of breath may occur.

Vitamin C is relatively nontoxic. Excess vitamin C may promote the formation of oxalate kidney stones. The tolerable upper intake level, or maximum intake level likely to pose no risk of adverse health effects in most individuals, was set at 2000 mg ascorbic acid per day from food plus supplements (Institute of Medicine, 1998).

### Vitamin K

Vitamin K refers to a group of compounds that are 2-methyl-1,4-naphthoquinones with a hydrophobic substituent at the 3-position. Phylloquinone (vitamin K<sub>1</sub>), which is synthesized by plants, has a 20-carbon phytyl substituent at the 3-position of the naphthoquinone ring. Menaquinones (vitamin K<sub>2</sub>) are synthesized by bacteria and have an unsaturated side chain, made up of four to thirteen isoprenyl units, instead of the saturated phytyl chain present in phylloquinone. Animal tissues contain both phylloquinone and menaquinones. In addition to these naturally occurring compounds with vitamin K activity, a synthetic form of vitamin K called menadione can be alkylated to an active form in the liver and is used in animal feeds. Human vitamin K supplements are phylloquinone.

Green vegetables are the major dietary source of phylloquinone: kale, spinach, broccoli, brussels sprouts, cabbage, and lettuce are rich sources. Some vegetable oils, especially soybean oil and rapeseed (canola) oil, are good sources. Menaquinones, which are obtained especially from liver, provide only a minor portion of the vitamin K needed to meet the requirement. The nutritional significance of menaquinones synthesized by bacteria in the lower bowel is uncertain.

The RDA for vitamin K for adults who are age twenty-five years and older is 65 and 80 micrograms for women and men, respectively (National Research Council, 1989). The RDA for males is provided by  $\frac{1}{3}$  ounce of spinach or kale,  $\frac{1}{3}$  cup of broccoli,  $\frac{2}{3}$  cup of shredded cabbage, or  $2\frac{1}{4}$  ounces of lettuce. Typical intake of vitamin K by adults is 70 to 100 micrograms per day.

Absorption of dietary vitamin K depends upon adequate lipid absorption. Vitamin K is incorporated into chylomicrons, along with other lipids, and ultimately is taken up by the liver as part of the chylomicron remnants. Vitamin K is stored in liver; the hepatic phylloquinone

pool turns over more rapidly than that of menaquinones. Vitamin K is excreted predominantly as metabolites and glucuronides; these are excreted primarily in feces via the bile, but significant amounts are also excreted in urine.

The hydroquinone form of vitamin K is required for the posttranslational modification ( $\gamma$ -glutamylcarboxylation) of a group of proteins (referred to as Gla proteins or vitamin K-dependent proteins) during their synthesis. Vitamin K serves as substrate, or coenzyme, for an enzyme that converts targeted glutamyl residues to  $\gamma$ -carboxyglutamyl (Gla) residues in these proteins. This posttranslational modification of glutamyl residues is essential for the normal physiological function of vitamin K-dependent proteins. Continued function of vitamin K in  $\gamma$ -glutamylcarboxylation reactions is dependent upon the recycling of oxidized vitamin K (vitamin K epoxide) back to the hydroquinone form (vitamin  $KH_2$ ).

Vitamin K-dependent proteins include four plasma clotting proteins (prothrombin, factor VII, Factor IX, and factor X), two plasma proteins involved in thrombin-initiated inactivation of factor V (protein C and protein S), plasma protein Z of uncertain function, and two bone proteins (osteocalcin, or bone Gla protein, and matrix Gla protein). At physiological pH, both carboxyl groups of each Gla residue are negatively charged, and these anionic residues are involved in the association of Gla proteins with  $Ca^{2+}$ .

Primary vitamin K deficiency is rare. Vitamin K-responsive hemorrhagic disease of the newborn can occur because of low vitamin K stores in the liver of the newborn and the low vitamin K content of human milk, along with other factors. In developed countries, commercial infant formulas are supplemented routinely with phyloquinone, and the practice of oral or intramuscular administration of phyloquinone to the newborn is almost universal. Vitamin K deficiency also has been reported in adults with low intakes of vitamin K who are receiving antibiotics and in patients subjected to long-term total parenteral nutrition without vitamin K supplementation. Vitamin K status should be of concern in disorders of lipid digestion or absorption and in persons treated with anticoagulant drugs that act by blocking reduction of oxidized vitamin K.

Toxic manifestations from ingestion of large amounts of vitamin K have not been reported. Mena-dione administration to infants has been associated with hemolytic anemia and liver toxicity, and should not be used for human supplements.

## Vitamin E

Vitamin E is the term used for all tocopherols and tocotrienols and their derivatives that exhibit vitamin E activity. Tocopherols are more important sources of vitamin E. Both the tocopherols and tocotrienols consist of a chromanol head and a phytyl tail. The side chain of tocopherols is saturated, whereas that of tocotrienols con-

tains double bonds at the 3', 7', and 11' positions. Four tocopherols and four tocotrienols occur naturally; they differ in the number and position of the methyl groups on the chromanol ring. The naturally occurring isomer of  $\alpha$ -tocopherol is the 2'R, 4'R, 8'R isomer, whereas synthetic tocopherols are mixtures of all eight possible stereoisomers.

Tocopherols in foods exist primarily as the free or unesterified forms. Ester forms (e.g.,  $\alpha$ -tocopheryl acetate or  $\alpha$ -tocopheryl succinate) are less susceptible to oxidation and are used for food fortification and for supplements. The 6-hydroxyl group on the phenolic ring is the site for esterification of fatty acids.

A variety of naturally occurring RRR- $\alpha$ -tocopherols and tocotrienols are supplied by foods. Tocopherols differ in their antioxidant and biological activities. Currently, the biological activity of various forms of vitamin E are expressed as units of activity in relation to that of all-*rac*- $\alpha$ -tocopheryl acetate, which is a common pharmaceutical or synthetic form of vitamin E. The unit used to express vitamin E activity is the  $\alpha$ -tocopherol equivalent ( $\alpha$ -TE) with 1 equivalent equal to 1.49 mg of all-*rac*- $\alpha$ -tocopheryl acetate or 1.0 mg of RRR- $\alpha$ -tocopherol. The majority of the tocopherols consumed in the diet are not  $\alpha$ -tocopherol, and  $\gamma$ -tocopherol accounts for more than half the estimated total tocopherol intake. Rich sources of vitamin E include vegetable oils, vegetable shortenings, margarines, mayonnaise, salad dressings, wheat germ, rice bran, nuts, seeds, peanut butter, eggs, potato chips, whole milk, and tomato products.

The RDA for vitamin E is 15 mg  $\alpha$ -TEs for adults. This amount of vitamin E could be provided by 4 teaspoons of soybean oil,  $\frac{2}{3}$  cup of margarine, 2 cups of whole milk,  $4\frac{1}{2}$  cups of green peas, or 2 pounds of salmon. The average intake of vitamin E from American diets is 11 to 13 mg  $\alpha$ -TEs daily in adults not taking vitamin E supplements.

Tocopheryl esters are hydrolyzed to free tocopherol in the small intestinal lumen, presumably by pancreatic esterases. Vitamin E is absorbed with other lipids, and the majority of the vitamin E is incorporated into chylomicrons in the mucosal cells of the small intestine. The chylomicrons are secreted into the lymph and then enter the circulation. Vitamin E is taken up by the liver in the chylomicron remnants and is then either stored in the parenchymal cells of the liver, incorporated into nascent very low density lipoproteins (VLDL) that are secreted into the blood stream, or excreted via the bile. Both vitamin E and its metabolites are primarily excreted in the feces via biliary secretion from the liver. Some metabolites are excreted in the urine.

Vitamin E is the major lipid-soluble, chain-breaking antioxidant found in plasma, red cells, and tissues, and it plays an essential role in maintaining the integrity of biological membranes. Among the biological functions proposed for vitamin E, the reaction of  $\alpha$ -tocopherol with

lipid peroxyl radicals to prevent uncontrolled free radical-initiated lipid peroxidation is the best understood. Whether other tocopherols have other roles is uncertain.

Patients with familial isolated vitamin E deficiency have clear signs of vitamin E deficiency (extremely low plasma vitamin E levels and neurological abnormalities—spinocerebellar dysfunction with progressive ataxia) but do not have fat malabsorption or lipoprotein abnormalities. Absence of hepatic  $\alpha$ -tocopherol transfer protein impairs secretion of  $\alpha$ -tocopherol into hepatic lipoproteins (VLDL) and appears to be responsible for the low plasma vitamin E status of patients with familial isolated vitamin E deficiency and the low delivery of vitamin E to tissues. In humans, low plasma levels of vitamin E are associated with shorter lifespans of red blood cells because of their increased susceptibility to hemolysis. Vitamin E deficiency is rarely associated with lipid malabsorption syndromes or lipoprotein abnormalities. Neurological symptoms occur in individuals with malabsorption syndromes as well as in individuals with familial isolated vitamin E deficiency.

Vitamin E is relatively nontoxic when taken by mouth. The upper tolerable intake level set by the Institute of Medicine (2000) is 1000 mg of  $\alpha$ -TEs per day from vitamin E supplements in addition to dietary intake. Consumption of more than this increases risk of hemorrhagic damage because vitamin E can act as an anticoagulant.

### Potassium

Potassium ( $K^+$ ) is distributed widely in the body and is the principal cation in intracellular fluids. Like sodium and chloride ions, potassium ions exist as free hydrated ions that bind only weakly to organic molecules. Potassium functions in the maintenance of electrolytic and osmotic balances or gradients. The distribution of potassium between the intracellular and extracellular fluids is the result of ion pumps and of the permeability characteristics of cell membranes. The  $Na^+$ ,  $K^+$ -ATPase pump, which moves 3  $Na^+$  out of the cell in exchange for 2  $K^+$  that are moved into the cell, is of particular importance.

Potassium is widely distributed in foods, especially in fruits and vegetables. Rich sources of potassium include fruits such as avocado, banana, cantaloupe, orange juice, and watermelon; vegetables such as lima beans, potatoes, tomatoes, spinach, and winter squash; and fresh meats.

Obligatory losses of potassium, which must be replaced, average about 800 mg of potassium per day. The estimated minimum requirement for potassium established by the National Research Council (1989) is 2 g per day for adults. Two grams of potassium are provided by 4 cups of fresh orange juice, 5½ small bananas, 5 medium potatoes, or ¼ pound of beef chuck. Typical Western diets provide about 3 g of potassium per day.

Over 90 percent of the potassium in the diet is absorbed from the gut into the circulation. However, al-

though nearly all of the dietary  $K^+$  is absorbed in the small intestine, there is normally some net secretion of  $K^+$  in the colon that results in loss of potassium in the feces. Absorption of dietary  $K^+$  causes a rise in the concentration of  $K^+$  in the plasma, and this immediately stimulates physiological mechanisms to promote rapid entry of  $K^+$  into cells so that a rapid rise in the plasma  $K^+$  concentration is prevented. Uptake of  $K^+$  by cells is essential in preventing life-threatening hyperkalemia. Nevertheless, in the long-term, to maintain  $K^+$  balance, the excess  $K^+$  from the diet must be excreted by the kidneys.

At typical potassium intakes, renal tubular secretion of  $K^+$  is required to maintain potassium balance. Renal secretion of  $K^+$  is under the control of various homeostatic regulatory mechanisms. The most important hormone regulating secretion of  $K^+$  is aldosterone, the release of which is triggered by a high concentration of  $K^+$  in plasma (or a low concentration of  $Na^+$  or by angiotensin II). When potassium intake is high, secretion of  $K^+$  by the colon as well as the kidney is increased to eliminate the excess potassium.

During potassium depletion, the kidney reabsorbs most of the filtered  $K^+$ , and essentially no  $K^+$  is secreted. The small amount of  $K^+$  excreted in the urine under these circumstances comes from the filtered  $K^+$  that escaped reabsorption.

The high concentration gradient of  $K^+$  between the intracellular fluid and the extracellular fluid is important for generation and maintenance of the normal resting membrane potentials across cell membranes and for excitability of nerves and muscles. Higher intakes of potassium may have beneficial effects in preventing hypertension.

Dietary deficiency of potassium does not occur under normal circumstances. Large losses can occur, by either gastrointestinal or renal routes, in cases of prolonged vomiting, chronic diarrhea, use of diuretic agents, some forms of chronic renal disease, and in some metabolic disturbances such as metabolic acidosis. Hypokalemia causes membrane hyperpolarization, and this can interfere with the normal functioning of nerves and muscles, resulting in muscle weakness and decreased smooth muscle contractility. Deficiency symptoms include weakness, anorexia, nausea, drowsiness, and irrational behavior.

Acute hyperkalemia can result from sudden enteral or parenteral increases in potassium intake to amounts of about 18 g per day for an adult. Hyperkalemia causes membrane depolarization, causing muscular weakness, flaccid paralysis, and cardiac arrhythmias. Severe hyperkalemia can cause cardiac arrest and death.

### Chloride

Chloride is the principal inorganic anion in the extracellular fluids of the body. Dietary chloride comes almost entirely from sodium chloride, and a small amount comes from potassium chloride. Thus, table salt and foods or

beverages that contain NaCl added during food processing or preparation are the major sources of chloride in the diet. The amount of chloride contributed by water is low compared to that contributed by salt.

The estimated minimum requirement for chloride is 750 mg/day for adults, which corresponds to about 1.3 g of sodium chloride per  $\frac{1}{4}$  teaspoon of table salt). Typical salt intake in the United States is higher than this. It is recommended that daily salt intake should not exceed 6 g because of the association of high intake with hypertension.

Loss of fluids through the skin, feces, and urine cause loss of both sodium and chloride. Chloride movement tends to parallel that of sodium, and loss of sodium usually is accompanied by a similar molar loss of chloride. Thus, conditions that cause loss of sodium (e.g., heavy losses through sweating, chronic diarrhea or vomiting, trauma, or renal disease) also cause loss of chloride and can result in hyponatremic metabolic alkalosis.

Chloride is essential for maintenance of fluid and electrolyte balance. Hydrochloric acid is an essential component of the gastric juice secreted by the stomach.

Deficiency of chloride does not occur under normal circumstances. Toxicity from excess intake of chloride is not known to occur, but water-deficiency dehydration can cause hyperchloremia.

**NUTRITION.** Food is comprised of nutrients that are classified by their role in the body: the energy-yielding macronutrients (carbohydrates, protein, and fat), the essential micronutrients (vitamins, minerals, and water), and numerous other components. Although micronutrients do not supply energy to fuel the body, they are indispensable for the proper functioning of the metabolic and regulatory activities in the body. Other nonessential nutrients, such as flavonoids, phytoestrogens, carotenoids, and probiotics, also may have important health-promoting properties, and investigations are ongoing. The daily intake of a variety of foods provides energy and nutrients that are essential to the health and well-being of an individual. The relationships among food intake, nutrition, and health define the field of nutrition. More fully, nutrition is the study of food, its nutrients and chemical components, and how these constituents act and interact within the body to affect health and disease.

The scope of the field has grown in recent years and the boundaries between the science of nutrition and many other biological sciences have blurred. For example, the science of nutrition includes chemistry to study how food ingredients interact with each other; physiology to investigate how nutrients within food are assimilated into body tissues; engineering to design new fortified foods; anthropology to explore why we chose to eat certain foods in centuries past; and psychology to determine what attitudes and behaviors influence our dietary patterns today. Nutritionists often have either a college or advanced degree in nutrition or a related field, whereas clinical (human) nutrition specialists will have graduate degrees, which may include medicine, and have completed an examination for certification. Registered dietitians are nutrition professionals who are often responsible for applying nutritional science to clinical practice to promote health and treat disease. Dietitians frequently work in hospitals but also may be employed in universities, public health departments, restaurants, the food industry, and exercise facilities. Similarly, given the broad

## PROFESSIONAL NUTRITION CREDENTIALS IN THE UNITED STATES

Commission on Dietetic Registration

American Board of Nutrition

National Board of Nutrition Support Certification

Certification Board for Nutrition Specialists

### Type of Certification\*

*DTR*: Dietetic Technician (A.A., B.S., B.A.)

*RD*: Registered dietitian (B.S.)

*CSP* or *CRD*: Board certified specialist in pediatric or renal nutrition

*FADA*: Fellow of the ADA (R.D. and Ph.D., M.S.)

Clinical Nutrition Specialist (M.D.)

Human Nutrition Specialist (Ph.D.)

*CNSP*: Certified Nutrition Support Physician (M.D.)

*CNSD*: Certified Nutrition Support Dietitian (R.D.)

*CNS*: Certified Nutrition Specialist (Ph.D., M.S.)

\* Type of education required for certification indicated in parentheses.

Italicized acronyms denote the professional credentials required for certification.

scope of the field, other nutrition professionals include but are not limited to physicians, biochemists, anthropologists, epidemiologists, geneticists, food scientists, and engineers.

For this review, the field of nutrition is divided into three major categories: (1) nutrition in research, (2) nutrition in clinical practice, and (3) nutrition in policy and education. An overview of nutritional research is presented, from how nutrients interact within the body and among themselves (nutritional biochemistry), to the investigation of the relationships between specific foods or food groups and the health status of populations (nutritional epidemiology). Research findings in the field provide the information needed to guide nutrition practice for the care of individuals as well as large groups of people. The development of nutrition policy comes from both research and clinical practice advances. Concise descriptions of each are given and a brief history of the field and projected directions of the future of the field are offered.

### Nutrition: A Historical Perspective

Numerous advances in the field of nutrition have occurred within the last century. The major focus of nutrition research and practice shifted from concern over which foods are required to avoid nutritional deficiencies and overt illness, to what foods and supplements may be consumed to promote optimal health. Functional foods are a part of the vocabulary, and energy bars, herbal remedies, and nutritional supplement products are now widely available.

In biblical times certain foods were understood to have special healing properties; however, the concept of nutrients as essential for health is relatively new. Recent discoveries in the field have been dependent on the development of scientific methods to analyze nutrient con-

tent and interactions. Therefore, though some vitamins were understood to be essential in the early part of the twentieth century, trace elements such as zinc and selenium were not considered essential for humans until the 1970s.

As the field of nutrition has developed, it has also expanded. In 1950 the history of nutrition science during the two previous centuries was summarized by Dr. Elmer McCollum in just under five hundred pages. It would likely take ten volumes of such texts to encapsulate the nutrition-related findings and proceedings from the latter half of the twentieth century. Accomplishments in the field of nutrition over the last century are highlighted in five major eras: (1) food as energy, (2) micronutrient deficiency diseases, (3) nutrition in public policy, (4) nutrition and chronic disease, and (5) nutrition for optimal health.

***Food as energy (1880–1920).*** By the end of the nineteenth century the major, energy-yielding components of food—protein, fat, and carbohydrate—had been identified, and nutrition research, especially concerning the metabolism of proteins and the energy composition of foods, was flourishing. Much of this work had been conducted in animals; therefore, the human nutrition experiments performed by Dr. W. O. Atwater (1844–1907) and colleagues were particularly novel. From their studies, the energy yield of carbohydrate, protein, and fat was derived (4, 4, and 9 kcal per gram, respectively), values that are still used today. Dr. Atwater also developed the first human calorimeter in the United States to measure energy expenditure. However, it was a pair of medical doctors, James Harris and Francis Gano Benedict, who perfected this methodology to establish standards for the energy needs of healthy individuals. Energy expenditure was measured in approximately 250 healthy men and women

at the Carnegie Institute Laboratory in Washington, D.C., and equations were derived from the data. The Harris-Benedict energy expenditure prediction equations for men and women, published in 1919, remain some of the most useful tools in clinical nutrition assessment today.

***Micronutrient deficiency diseases (1920–1940).*** The period between 1920 and 1940 brought about a paradigm shift in the understanding of the etiology of some common diseases. Until this time it was thought that all disease resulted from poor sanitation and hygiene; therefore, bacteria, mold, and toxins were identified as the likely cause of disease. As Alfred Harper has suggested, “the concept that a disease might be caused by a deficit of a substance that was nutritionally essential was beyond the grasp even of most nineteenth-century physicians and scientists” (p. 217). In order to combat disease as well as increase shelf life, food was sterilized, milled, and polished to reduce the danger of ingesting bacteria, mold, and toxins. Despite these efforts, pellagra, beriberi, and infantile scurvy actually increased in prevalence. In a number of studies conducted by Dr. Joseph Goldberger from 1914 to the 1920s, where the diets of individuals suffering from pellagra were compared to those of healthy individuals, foods that decreased the presence of diarrhea and dementia in pellagrous individuals were identified. From his work it was later determined that pellagra was due to a diet poor in the vitamin niacin and not infection. At approximately the same time, Dr. Christiaan Eijkman (1858–1930) won a Nobel Prize in medicine (1929) for the discovery of the “antineuritic” vitamin thought to be responsible for curing beriberi. Through his experiments, in which chickens were fed human hospital diets, combined with studies of beriberi in prisoners who survived on polished rice, he hypothesized that the hull of the rice grain contained an antidote to the neurological disorder. Although not completely correct, his observations led to the discovery of the essential vitamin thiamin.

As Kenneth J. Carpenter summarized, “new technologies of food processing that have obvious advantages may also have a downside” (p. 227). While technology decreased infectious disease and increased the shelf life of food products, it inadvertently led to nutritional deficiencies. The heat-sterilization of cow’s milk, which destroyed vitamin C, was related to the outbreak of infantile scurvy in well-to-do families. The practices of polishing rice and degerming corn to increase grain stability also led to increased prevalence of beriberi (thiamin deficiency) and pellagra (niacin deficiency), respectively.

***Nutrition in public policy (1920–1964).*** One of the most fruitful periods in the history of public health nutrition followed on the coattails of World War I. It became possible to manufacture the micronutrients that had been identified by chemists as essential for health cheaply and efficiently. In 1922 the first of a series of public health efforts at eradicating nutrient deficiency in the United

States was initiated by the voluntary addition of iodine to salt (see Table 1). The fortification of other foods was used to address rampant public health problems such as rickets (vitamin D), beriberi (thiamin), pellagra (niacin), and dental caries (fluoride). Since the initiation of fortification policies in the United States, clinically evident nutritional deficiencies have been virtually eliminated.

The first attempt at defining nutritional requirements was directed toward the prevention of nutrient deficiencies in military personnel during World War II. In the early 1940s the Food and Nutrition Board of the National Academy of Sciences reviewed the scientific evidence and developed the Recommended Dietary Allowances for energy, protein, and eight essential vitamins and minerals. The first national food supplementation program was initiated in 1946 (National School Lunch Act) to improve the dietary intake of children from economically disadvantaged families. Other national food assistance programs were added over the next fifty years.

***Nutrition and chronic disease (1960–1990).*** The last forty years of the twentieth century saw continued discovery in the field of nutritional biochemistry and a new research emphasis on the role of nutrition in the cause of and treatment for chronic disease. Disease patterns shifted from infectious and nutrient deficiency diseases to increasing rates of cardiovascular disease, diabetes, cancer, and osteoporosis. Nutrient deficiencies, when present, were often secondary to restrictive dietary habits, economic deprivation, or the presence of another disease that altered nutrient metabolism. The more pressing problem now was the change in the American lifestyle and a dietary shift from too little to too much. Modern household technologies increased productivity in housework but decreased physical activity, and the home-cooked family meal became a thing of the past. Varied diets consisting of whole grains, fruits, and vegetables gave way to convenience foods resulting in a much higher consumption of fat and sugar. Results from the Framingham Heart Study were perhaps the first glimpse into the relationship between fat intake and cardiovascular disease and the realization that each type of fat plays a specific role in health and disease. During this era, links among fat intake, serum cholesterol, and cardiovascular disease were studied thoroughly, and the reasons for the increasing prevalence of obesity in the United States were explored. In 1985 Michael Brown and Joseph Goldstein were awarded the Nobel Prize in medicine for their work on the regulation of cholesterol metabolism and its influence on arteriosclerosis.

The essentiality of macrominerals (e.g., calcium, phosphorus, sodium) was understood in the 1850s. However, it was not until technological advances triggered an explosion of new research that trace and ultra-trace elements were identified as essential for humans. Working together, nutritionists, biochemists, biologists, immunologists, geneticists, and epidemiologists uncovered the mysteries behind minerals such as zinc, selenium,

TABLE 1

<b>Significant policies and recommendations in nutrition (1901–2001)</b>		
<b>Date</b>	<b>Nutrition policies and recommendations</b>	<b>Description</b>
1917	Food Guide, “5 Food Groups”	Food groups included flesh foods, breads/cereals, butter/fats, fruits and vegetables, and sweets (USDA).
1922	Iodine fortification	Iodized salt was initially added to salt (60 mg/g salt) in Michigan, goiter virtually eradicated by 1927.
1932	Vitamin D fortification	Vitamin D was added to milk at a minimum of 400 IU/quart. Was also added to some margarine.
1941	Enrichment with iron, niacin, riboflavin, and thiamin	Iron, niacin, riboflavin, and thiamin were added to refined wheat flour, and eventually to bread, pasta, rice, and cereal grain products.
1943	Recommended Dietary Allowances, 1st edition (United States)	Purpose: “To serve as a guide for planning an adequate diet for every normal person.” (FNB/NRC)
1945	Fluoride fortification	Voluntary artificial fluoridation of municipal water supply in the United States; currently, 62 percent of U.S. population drinks fluoridated water.
1946	Food Guide, “Basic 7”	Food groups included milk, meat, green/yellow vegetables, citrus fruits, potatoes/other vegetables, bread/cereal, and butter/margarine (USDA).
1946	National School Lunch Act	It provides nutritionally balanced, low-cost, or free lunches to nearly 27 million children each school day. The program was established under the National School Lunch Act, signed by President Harry S Truman.
1958	Daily Food Guide, “Basic 4”	Food groups included meat/eggs/fish, milk/dairy, fruit/vegetables, and bread/cereals (USDA).
1964	Food Stamp Act	The first Food Stamp Act was started as a pilot project in 1961. The current law was enacted in 1977 and is amended regularly by the Congress. Purpose is to end hunger and improve nutrition and health. It helps low-income households buy food for a nutritionally adequate diet.
1975	National School Breakfast Program	The School Breakfast program began as a pilot project in 1966 under the Child Nutrition Act. The purpose was to ensure that all children have access to a healthy breakfast at school to promote learning readiness and healthy eating behaviors. It provides nutritionally balanced, low-cost, or free breakfasts to 7.4 million children each school day.
1971–1974	National Health and Nutrition Examination Survey (NHANES)	The first of a series of surveys to assess the health and nutritional status of the U.S. population (NCHS/CDC).
1974	Special Supplementary Nutrition Program for Women, Infants, and Children (WIC)	Nonentitlement program designed to improve the intake of protein, vitamins A and C, calcium, and iron, to low-income, pregnant, and lactating women and children less than 5 years old.
1980	Dietary Guidelines for Americans: Nutrition and Your Health	First set of recommendations for individuals to guide food choices without specifying amounts (USDA/DHHS).
1985	Continuing Survey of Food Intakes of Individuals (CSFII)	The first of a series of surveys to provide information on the dietary status of the U.S. population and monitor changes in dietary intakes (ARS).
1988–1994	NHANES III	National Health and Nutrition Examination Survey, noted the significant increase in obesity in the United States (NCHS/CDC).
1989	RDA, 10th edition	Definition: the level of intake of essential nutrients that . . . meet the known nutrient needs of practically all healthy persons.
1989	VI. Diet and Health: Implications for Reducing Chronic Disease Risk	Thorough review of the evidence on which dietary guidelines are based. Specific evidence provided on intake of fat, fruit and vegetables, protein, salt, alcohol, calcium, fluoride, and physical activity (FNB).
1990	VII. Nutrition Labeling and Education Act (NLEA)	This act made standardized nutrition labeling on food products in the United States mandatory. There are now 11 health-related claims that are approved to be used in advertising on food packages (FDA).
1992	Food Guide Pyramid	Eating guide based on the RDA that also considered salt, fat, and sugar intake (USDA/HNIS).
1994	Dietary Supplement Health and Education Act (DSHEA)	Exempts any product labeled as a dietary supplement from FDA regulatory approval. Permits structure/function claims without prior FDA authorization.
1997	Dietary Reference Intakes (DRI)	This was the first in a series of revised recommendations now called DRI, which replaces the RDA. This report included recommendations for calcium, phosphorus, magnesium, vitamin D, and fluoride.
1998	Folate fortification	Fortification of all breads, pasta, rice, flour, and breakfast cereals with folate to decrease the risk of neural tube defects in women of childbearing age. Program initiated in United States, Mexico, and Canada.
1998	Dietary Reference Intakes (DRI)	Second series of the DRI for thiamin, riboflavin, niacin, vitamins B <sub>6</sub> and B <sub>12</sub> , folate, pantothenic acid, biotin, and choline.
2000	Dietary Guidelines for Americans, 4th edition	The dietary guidelines are updated about every 5 years. They provide nontechnical suggestions for healthy dietary patterns and activity (USDA/DHHS).
2001	Dietary Reference Intakes (DRI)	Third series of the DRI for vitamins A and K, arsenic, boron, chromium, copper, iodine, iron, manganese, molybdenum, nickel, silicon, vanadium, and zinc.

copper, molybdenum, and chromium. Scientists first recognized human zinc deficiency in the mid-1960s. Severely growth-retarded, young Middle Eastern men were anemic, extremely lethargic, and hypogonadal. Their diet consisted mainly of wheat bread with little animal protein. When their diets were supplemented with zinc, their lethargy, growth, and genital development improved.

**Nutrition for optimal health (1990–present).** In the understanding of nutrition, the American public experienced yet another paradigm shift in the 1990s. They wondered if all nutrients that provided a health benefit needed to fit the traditional definition of “essential nutrient.” As a result of this question, herbal and botanical extracts, phytochemicals, and other alternative nutritional therapies to promote optimum health were explored. In 1999 the U.S. market for functional foods alone was estimated to be \$6 billion (Hasler, p. 504) and it continues to grow by approximately 12 percent each year. The explosion of this market is likely due to the increase in social acceptance, changes in regulations, the booming economy of the 1990s, and the targeting of products to particular populations. The scientific validation of some therapies also is of increasing interest.

Pharmacological uses (larger amounts than required to prevent deficiencies) of essential nutrients are being explored. Although much of the current interest in megavitamin supplementation began in the 1990s, the work of Dr. Linus Pauling in the 1970s initiated the movement. Pauling was the only individual to be awarded two unshared Nobel prizes for his work in chemistry (1954) and peace (1962). In the field of nutrition, however, he is noted most for his unproven theories regarding the potential protective role of vitamin C on the common cold, cancer, and heart disease. Pauling himself reportedly took up to six hundred times the recommended daily amount of vitamin C. Given that many individuals also practice a “more must be better” approach, the national recommendations for nutrient intake now include guidelines for safe upper limits for individual nutrient intakes.

## Nutrition in Research

Experimental nutrition research is one aspect of the science of nutrition. Nutrition research is conducted to answer questions raised both in clinical practice and policy. Research in nutrition can focus on individual cells, whole animals or humans, or entire populations, and often overlaps with research in genetics, biochemistry, molecular biology, toxicology, immunology, physiology, and pharmacology.

**Nutritional biochemistry.** Nutritional biochemistry is the backbone to the understanding of the structure and function of nutrients within food and the body. Nutrients serve as cofactors for enzymes, components of hormones, and participants in oxidation/reduction reactions through metabolic processes. Though required in small amounts,

nutrients are essential for body growth, sexual development and reproduction, psychological well-being, energy level, and the normal functioning of most organ systems in the body. Nutritional biochemists study the functional roles of vitamins and minerals in the body, metabolic blocks that occur from deficiencies, the effects of hormones on nutrient metabolism, and interactions among nutrients within the body. In the 1990s a whole new area of research emerged that focuses on relationships between nutrition and genetics. An example of this type of study includes the identification of a genetic defect in folate metabolism (C677T), which increases a woman’s risk of delivering a baby with a neural tube defect.

**Food science.** Food science is the study of the composition of food materials and the reaction of food to processing, cooking, packaging, and storage. Food science integrates knowledge of the chemical composition of food materials; their physical, biological, and biochemical behavior; the interaction of food components with each other and their environment; pharmacology and toxicology of food materials, additives, and contaminants; and the effects of manufacturing operations, processes, and storage conditions.

The potential beneficial role of functional foods in the American diet has gained attention and recent food science research focuses on the development of such foods. Functional foods are generally defined as those that provide health benefits beyond basic nutrition, and include fortified, enriched, or enhanced foods, and whole foods, which have high levels of protective nutrient components. Examples of these foods include orange juice with added calcium or echinacea, or snack foods with antioxidants, fruit-flavored candy with vitamin C, various soy products, and margarine with added plant sterols. Factors that drive the market for such foods include a growing general public interest in nutrition and its impact on health, an aging population that is more concerned with health, research findings receiving media attention, and an increasingly unregulated consumer food market.

**Human nutrition.** Human nutrition, or clinical nutrition, research is that which focuses on the study of nutrients within the living human body. Although biochemical studies are extremely informative, until the nutrient is added to or depleted from the diet, the effects on individuals can only be hypothesized. Human nutrition research includes the study of individual nutrient requirements (e.g., nutrient intake assessment, energy expenditure assessment, nutrient turnover balance studies, and nutrient bioavailability), the effects of nutrients on body growth (e.g., body composition techniques, anthropometry, pubertal assessment), and the dietary, physiological, or disease factors that influence nutrient requirements. In the 1990s one important human nutrition study found that increasing folic acid intake in young women reduces the incidence of neural tube defects (spina bifida) in their babies.

**Nutritional epidemiology.** Nutritional epidemiology is the science of systematically studying the relationships between food choices and health status. Epidemiological studies are particularly valuable in understanding complex relationships between food intake (dietary exposure) and determinants of diseases with multiple etiologies and long latent periods. Examples of such studies include the relationships between low folic acid intake and increased incidence of spina bifida, and elevated saturated fat intake and elevated risk of arteriosclerosis. There are, however, limitations to these studies in that they describe relationships rather than prove cause and effect. Frequently, clinical trials and intervention studies are used as follow-up studies to evaluate more fully the questions raised by epidemiological evidence.

### Nutrition in Clinical Practice

Scientific evidence continues to mount regarding the key roles that nutrients and their metabolism play in the prevention of the most common chronic diseases. Half of the leading causes of death in the United States (heart disease, cancer, stroke, and diabetes) are associated strongly with unhealthy eating habits. Clinical nutrition is the practice of applying research evidence to aid in the care of individuals with or at risk for diet-related diseases. These principles are used to develop individualized nutrition care plans. Generally, diseases may affect nutritional status by (a) decreasing the intake of nutrients, (b) altering the metabolism of nutrients (or unusual losses), or (c) altering energy expenditure. Alternatively, as mentioned briefly above, poor nutritional status can lead to disease. For example, zinc deficiency can decrease the function of the immune system that in turn leads to increased risk for diarrhea and infectious diseases.

Assessment of nutritional status is essential for identifying undernourished and overnourished states (obesity is now a major health problem) and estimating the optimum intake to promote normal growth and well-being. Nutritional assessment has several components, including the evaluation of dietary intake, growth status, body composition, energy expenditure, and biochemical measures of nutritional status in the context of a medical history, diagnoses, and current therapy. These data are used to develop individualized nutritional care plans, which may include recommendations for total energy intake, adjustments in the diet to increase or decrease the consumption of certain foods, and possibly the inclusion of nutrient supplements. For patients who cannot be fed orally, more technology-based nutritional support is used to maintain or improve nutrient intakes and nutritional status. This involves either feeding the patient through a tube directly into the stomach or intestine (enteral) or through an intravenous line directly into the bloodstream (parenteral). Because malnutrition will add to complications of illness and prolong the illnesses and hospitalization, appropriate assessment of the patient is extremely important. In the complex and rapidly changing context

### DEFINITION OF TERMS

**Nutrition:** the study of foods, their nutrients, and other chemical components; their actions and interactions in the body; and their influence on health and disease.

**Nutritional Science:** the body of scientific knowledge that relates to the processes involved in nutrition.

**Health:** a state of optimal well-being—physical, mental, and social; relative freedom from disease.

**Functional Foods:** foods that provide a health benefit beyond basic nutrition.

**Essential Nutrient:** a substance that must be obtained from the diet because the body either cannot make it or cannot make adequate amounts.

**Enteral Nutrition:** nutrient solutions delivered into the gastrointestinal tract (e.g., stomach, small intestine) through a tube inserted through the nose or directly into the stomach.

**Parenteral Nutrition:** nutrient solutions delivered directly into the bloodstream through an intravenous catheter.

of critical illness, individualized nutrition assessments are crucial and require the sequential monitoring of all patients to maintain appropriate nutritional care plans.

It is unlikely that individuals who have not been seriously ill have had the opportunity to seek the counsel of a trained nutritional professional for developing an individualized diet plan. The average American displays a keen interest in how nutrition affects his or her health, and is disappointed with the information physicians are able to provide because traditional medical training has limited nutrition content. Therefore, greater numbers of individuals are seeking nutrition information for themselves, and using the information to self-diagnose and self-prescribe. The advances in communications technology, particularly the explosion of information on the World Wide Web, allow the ready accessibility of sound nutritional advice, and substantial amounts of quackery. Without training and a significant amount of time dedicated to the task, it is difficult to decipher truth from fraud. Future directions in nutritional education likely will include tools to aid Americans in deciphering information, particularly from the Internet, in order to make educated choices to optimize their diets and live healthier lives (see Table 2).

### Nutrition in Public Policy: Monitoring and Education

Nutrition in public health or nutrition policy generally is regarded as the combined efforts taken toward im-

proving nutrition and health status of populations. With increasing emphasis on health promotion and disease prevention, there is a proliferation of nutrition-related disease prevention, screening, and education programs targeted at increasing fiber, fruit, and vegetable intake, and reducing saturated fat intake. Additionally, a number of food assistance programs and mandated food fortification programs have been instituted, all promoting a healthy diet and lifestyle.

Nutrition research, public policy programs, and nutrition surveillance systems work synergistically like spokes on a wheel. Evidence obtained from scientific research is used to set nutritional recommendations such as the Dietary Reference Intakes and the Dietary Guidelines for Americans. These standards are used to judge the adequacy of the American diet, provide the basis for nutrition labeling of foods, formulate special diets, and guide the development of food fortification and nutrition policy developed to assist those who are at nutritional risk. Specific food assistance programs (such as, food stamps, Special Supplementary Nutrition Program for Women, Infants, and Children) are targeted at specific economically disadvantaged and nutritionally at-risk populations. Fortification programs generally are less specific, but some target at-risk populations through specific foods, for example, vitamin D-fortified milk to prevent rickets in young children. Finally, the wheel is completed by nutrition monitoring programs that are used to evaluate the effectiveness of instituted policies. The National Health and Nutrition Examination Survey (NHANES) and the Continuing Survey of Food Intake of Individu-

als (CSFII) are ongoing monitoring tools used to assess the population's nutrient intakes, nutrition and health status, and knowledge and attitudes about health.

Perhaps most important, public health nutrition includes the dissemination of scientific findings, the explanation of dietary recommendations, and outreach of federal assistance programs. The responsibility of communicating experimental findings in an understandable form falls on nutrition scientists, journalists, educators, and the public. The scientists are responsible for interpreting the research findings into a form that is understandable to the general public. Journalists are responsible for communicating the scientific message in an objective way, and the public is responsible for pursuing an accurate understanding of the issues. Various government agencies have the responsibility to organize and administer the myriad of nutritional policies and programs, and to communicate information regarding these programs to the public.

### The Future of Nutrition and Food Science

In the twentieth century nutrition research, practice, and public policy shifted from a focus on the quantitative aspects—to ensure food security and eradicate nutritional deficiencies—to a greater attention on the qualitative aspects—to achieve optimal, balanced, dietary intakes. In the twenty-first century nutrition research, practice, and policy will likely explore the following areas:

- relationships between human genetics and nutrition, the role of genetically modified foods in human health,
- the relationship of nonfood substances in the promotion of health and the bioengineering of functional foods,
- the promotion of economic growth and food security in developing nations to prevent or delay the undesirable health effects of malnutrition, and
- the prevention and treatment of the obesity epidemic in children and adults.

Relationships between food intake and human health will continue to be of great public interest, and nutrition and food scientists will face new challenges in a faster-changing environment.

**NUTRITIONAL ANTHROPOLOGY.** Many cultural anthropologists and sociologists who are interested in food and food systems examine the interrelation-

ships of social, cultural, and economic factors as they relate to food use. In contrast, nutritional anthropology refers to a field of study at the interface of anthropology and nutritional sciences focused particularly on understanding how the interactions of social and biological factors affect the nutritional status of individuals and populations. This does not mean that all research in nutritional anthropology involves measurement of nutritional status, and many studies in this field do not include biological outcomes in their research design. However, they differ from studies in the "anthropology of food" because their basic aim is to understand how the physical well-being of humans is affected by their food systems, while cultural anthropologists and sociologists analyze food use in order to understand how social and cultural systems work.

In their investigations, nutritional anthropologists use methods from both the social and biological sciences, which they also draw on in developing theories and testing hypotheses. Occasionally, they turn to humanistic scholarship as a source of insights into the cultural and historical aspects of food. The field can be characterized, therefore, as a biocultural discipline, which emphasizes the importance of integrating multiple perspectives on human behavior and experience in explaining nutrition.

The types of research undertaken by nutritional anthropologists can be classified into the following main categories: (1) sociocultural processes and nutrition; (2) social epidemiology of nutrition; (3) cultural and ideational systems and nutrition; (4) physiological adaptation, population genetics, and nutrition; and (5) applied research for nutrition programs.

Investigations in the category of sociocultural processes and nutrition are often focused on large-scale processes of change, such as globalization, modernization, urbanization, changing women's roles, and technological change in order to understand how these processes affect food and nutrition. While many investigators conduct studies in which they examine the effects in a specific location of a particular manifestation of change (for example, rural to urban migration in a particular developing country), others are concerned with understanding how large-scale changes have affected nutritional conditions across many populations. For example, nutritional anthropologists have studied the consequences for nutrition of a shift from foraging-hunting to agriculture. Studies of the effects on nutrition of a shift from subsistence farming to cash cropping are another example.

Nutritional anthropological research that falls into the category of social epidemiology and nutrition includes a range of topics, for example, describing how particular social and cultural factors place people at risk for nutritional problems or identifying health problems related to nutrition. Among the topics that have attracted attention are the social and ecological determinants of vitamin A deficiency and other micronutrient deficiencies, interactions of socioeconomic and cultural factors that

adversely affect growth in infants and young children, and the functional consequences of malnutrition in childhood and adulthood.

Studies in the area of cultural and ideational systems and nutrition are often aimed at understanding how particular beliefs relate to food selection, including food prescriptions and proscriptions. Among the topics investigated by nutritional anthropologists who link their work to public health issues are the ways culturally structured food avoidances during pregnancy or childhood illness affect health outcomes. For example, studies have been conducted on how beliefs about illness and food affect the treatment and household management of children with diarrhea.

There has been a long-standing interest among biocultural anthropologists in the interactions of cultural, physiological, and genetic adaptations in relation to food systems and nutritional patterns. One type of research that falls within this general category includes studies of behavioral adaptations that permit people to create and sustain diets that, over the long run, would be untenable biologically without such adaptations. For example, in Central America, ancient cultures developed the technique of soaking maize kernels in an alkaline solution, which improves its amino acid composition and the bioavailability of the B vitamin, niacin. Without these improvements, a population that subsisted on maize as its primary staple food would be at risk of serious malnutrition.

Another area of research in nutritional anthropology is the relationship between genetic variability in populations and food consumption patterns. A specific topic that falls within this area is the matter of lactose tolerance. Anthropologists have sought to understand how it is possible for adults in some populations to consume milk when the common pattern is for humans to lose their capacity to digest lactose after childhood. The role of this genetic trait has been explored in relation to the development of dairy-based food economies in northern Europe and some regions in Africa. It is likely that there will be an expansion of this type of research with the development of new techniques and knowledge in nutritional genomics.

In addition to conducting basic research, some nutritional anthropologists also engage in applied research, undertaken in direct support of public health activities. Often, investigations in this category involve community-level investigations, although applied nutritional anthropology may also be carried out for the purpose of informing national or international nutrition policy and planning. Studies at the community level may focus on identifying the sociocultural factors to be taken into account in instituting intervention activities (formative research) or in process evaluations to see how these factors are affecting the utilization of programs.

Applied anthropological studies in nutrition and health have been facilitated by the development of man-

uals for Rapid Assessment Procedures (RAP) or Focused Ethnographic Studies (FES). For example, with the aid of manuals, short-term qualitative studies have been conducted in planning interventions to improve vitamin A status in deficient populations and for interventions intended to improve the feeding of infants and young children.

As would be anticipated for a field that cuts across the disciplinary boundaries of the biological and social sciences, nutritional anthropology is eclectic in the scope of its theories and methods. Within that broad scope, however, one can identify a number of commonalities, including: (1) a focus on populations rather than studying individuals without consideration of the larger group of which they are a part; (2) a focus on communities and households as key social units that affect nutrition; and (3) a mixed method approach that utilizes both qualitative and quantitative techniques for data collection and analysis.

**NUTRITIONAL BIOCHEMISTRY.** Nutritional biochemistry is one of the academic foundations that make up nutritional sciences, a discipline that encompasses the knowledge of nutrients and other food components with emphasis on their range of function and influence on mammalian physiology, health, and behavior. Nutritional biochemistry is a subdiscipline that is made up of the core knowledge, concepts, and methodology related to the chemical properties of nutrients and other dietary constituents and to their biochemical, metabolic, physiological, and epigenetic functions. A primary focus of research in nutritional biochemistry is the scientific establishment of optimal dietary intakes (Dietary Reference Intakes or DRIs) for every nutrient and food component throughout the life cycle (Thomas and Earl, 1994; Standing Committee, 1998).

Nutritional biochemistry is an integrative science whose foundation is derived from knowledge of other biological, chemical, and physical sciences, but it is distinguished in its application of this knowledge to understanding the interactive relationships among diet, health,

### CORE KNOWLEDGE THAT DEFINES NUTRITIONAL BIOCHEMISTRY

- Structure and function of nutrients and other dietary constituents
- Chemical structure and metabolic functions of essential and nonessential nutrients
- Physiological and biochemical basis for nutrient requirements
- Motifs of absorption and transport of nutrients
- Integration, coordination, and regulation of macro- and micronutrient metabolism
- Regulation of nutrient metabolism and nutritional needs by hormones and growth factors
- Interaction of nutrients with the genome; nutrient control of gene expression; DNA stability
- Dietary bioactive components (functional foods)—nontraditional roles of nutrients
- Food, diets, and supplements
- Food sources of nutrients and factors affecting nutrient bioavailability
- Effect of food processing and handling on nutrient content and bioavailability
- Nutritional toxicology—upper limits of intake; nutrient–nutrient and drug–nutrient interactions
- Dietary Reference Intakes (DRIs); Food Guide Pyramid
- Nutrient supplements—risks/benefits, life stage, bioavailability
- Molecular markers of nutrient intake—gene arrays and analytical chips
- Nutrition and disease
- Impact of disease and genetics on nutrient function and requirements
- Genetic basis of inherited metabolic disease

SOURCE: Allen, Lindsay H., Margaret E. Bentley, Sharon M. Donovan, Denise M. Ney, and Patrick J. Stover, "Securing the Future of Nutritional Sciences through Integrative Graduate Education." *Journal of Nutrition* 132 (2002): 779–784.

and disease susceptibility. For example, nutritional biochemistry is rooted in analytical methodology that permits the purification of individual nutrients and the determination of their structures, as well as in classical biochemical approaches that identify metabolic pathways and elucidate the role of dietary components in regulating metabolism and gene expression. Additionally, human genetic studies of inherited inborn errors of metabolism, such as phenylketonuria, have contributed to core nutritional biochemical knowledge by revealing important interrelationships among nutrition, metabolism, and genotype and their interactions during normal and abnormal human development.

Knowledge generated from nutritional biochemistry research forms the foundation upon which nutrition-based public health interventions are designed and implemented. Many common diseases and disabilities afflicting human populations in both developing and developed countries result from general malnutrition, deficiencies of specific nutrients, or overnutrition. Inadequate diets or poor dietary habits are associated with increased risk for morbidity and mortality, including birth defects, diabetes, cardiovascular disease, obesity, and certain cancers. Specific nutrients, food components, or metabolites, singularly or in combination, can contribute to risk for disease or, alternatively, can be protective by preventing disease. Furthermore, associations among dietary components and diseases are strongly influenced by subtle genetic variation, such as single nucleotide polymorphisms, which are prevalent in all human populations. Research-based diet therapies and strategies to decrease the incidence of nutrition-related diseases have a successful history of improving public health and individual quality of life. Such strategies include (1) the fortification of grain products with folic acid to decrease the incidence of common birth defects (spina bifida), (2) the iodination of table salt to prevent cretinism, a developmental disorder associated with severe neurological and cognitive deficits in children, and (3) the promotion of diets low in cholesterol to prevent and to manage cardiovascular disease. These nutrition-based interventions have impacted the quality of life for individuals, and the monetary effects associated with the amelioration of these disorders have significantly benefited health care systems and national economies.

Current research and discovery in nutritional biochemistry is focused broadly in several areas, including nutritional genomics and metabolomics. Nutritional genomics is the study of genome–nutrient interactions and includes (1) the role of nutrients and dietary components in regulating genome structure, expression, and stability, and (2) the role of genetic variation on individual nutrient requirements. Nutritional metabolomics is the study of metabolic pathways and networks and includes (1) the regulation of metabolic pathways and networks, by nutrients and other food components, and (2) the establishment of analytical methods that “profile” human

serum and urinary metabolites to assess nutritional imbalances and disease risk. It is anticipated that knowledge derived from these new approaches will enable nutrient requirements to be tailored to an individual’s genetic profile for optimal health throughout the life cycle. In addition, information obtained from these new technologies will inform efforts (1) to improve or to enhance the food supply through the targeted introduction of traditional or novel foods, (2) to fortify food chemically with specific nutrients, or (3) to enhance crops genetically for higher nutrient content or quality.

Nutritional sciences academic training programs with a strong emphasis in nutritional biochemistry reside in medical colleges (e.g., Columbia University), schools of public health (e.g., Harvard University), and land grant universities (e.g., Cornell University). Nutritional sciences training programs can be independent units, jointly administered or affiliated with programs of toxicology, biochemistry, animal sciences, food sciences, and various medical programs. Academic faculty in nutritional biochemistry can be expert in many disciplines, including chemistry, biochemistry, genetics, and physiology. Therefore, individual nutritional sciences programs with distinct nutritional biochemistry concentrations are highly unique. Nutritional biochemists establish careers in teaching and research within universities, governmental and regulatory agencies, and the food, pharmaceutical, or biotechnology industries. Nutritional biochemists may also work in fields related to public policy, health care, or product development and marketing in the food industry.

**NUTRITIONISTS.** The field of nutrition is a broad one and has a wide variety of individuals working in it. Self-styled experts abound—based on the premise that they have eaten all of their lives, have grown, and are healthy adults, they regard themselves as nutrition experts. Unfortunately, it is not quite this easy to become a nutritionist. Cooks, chefs, science teachers, and many allied health professionals may have taken a course or two in nutrition during their training, but this does not qualify them as nutritionists either. Nutritionists have undergone rigorous educational programs in the sciences and have studied nutrients and other components of food in depth.

For the purpose of this discussion, four different types of nutritionists will be described along with the educational pathways needed to qualify for each position. These include the nutrition scientist, the public health

nutritionist, the dietitian (known in the United States as the registered dietitian or RD) and the dietetic technician (known as the dietetic technician, registered, or DTR in the United States). Each of these groups develops different skill sets, and each group is responsible for carrying out different functions in the broader field that is nutrition.

#### Nutrition Scientists

Nutrition scientists are those individuals who use the scientific method to study nutrients, both as individual compounds and as they interact in food and nutrition. The role of the nutrition scientist is to develop new knowledge related to nutrients or nutrition or to develop new processes or techniques to apply existing knowledge. For example, nutrition scientists have been involved in developing food preservation processes, determining nutrient requirements for various animal species, describing how individual nutrients function within the cells of the human body, and identifying nutrition-related problems in various populations.

Nutritionist scientists may have their basic training in nutrition or in a related field such as biochemistry, microbiology, cell biology, epidemiology, toxicology, agriculture, or food science. In most cases, they hold a PhD in their respective field of study. Sometimes, they hold another terminal degree such as an MD or a doctorate in public health (DrPH). Other nutrition scientists do not hold a terminal degree but are trained at the master's degree level and may assist in laboratories or in fieldwork. The characteristic that defines the nutrition scientist is not the field in which the training occurred, but the area in which the person is working. If scientists are conducting research with food, nutrients, or the nutritional status of groups, individuals, or animals, it is appropriate for them to be known as nutrition scientists. In the United States, the universities that train individuals to be nutrition scientists are regionally accredited, but the discipline-specific programs are not.

#### Public Health Nutritionists

Public health nutritionists are professionals who view the community as their client. They specialize in diagnosing the nutritional problems of communities and in finding solutions to those problems. Some classic examples of public health nutrition interventions include the fortification of salt with iodine to prevent goiter or the enrichment of grain products with B vitamins to prevent deficiency diseases like pellagra or beriberi.

Public health nutritionists are often dietitians who hold a bachelor's degree in applied nutrition. In addition, they study public health theory and practice at the master's degree level, earning a master's degree in public health (MPH). The curriculum for the MPH includes coursework in epidemiology, advocacy, public policy, program management, grant writing, and social marketing. Programs in public health nutrition may accept stu-

dents whose bachelor's degree is in a field other than nutrition; in that case, they also do graduate work in nutrition. In the United States, there is an organization known as the Association of Graduate Programs in Public Health Nutrition, Inc. that establishes voluntary guidelines for knowledge, skills, and competencies for public health nutritionists.

### Dietitians

Dietitians, RDs in the United States, are practitioners who translate the science of nutrition into practice for individuals and groups. Though dietitians may work in a variety of settings, they traditionally practice in the areas of clinical nutrition, food service, or community nutrition. RDs hold bachelor's degrees and have completed a supervised practice program known as a dietetic internship.

The profession of dietetics is self-regulating. Undergraduate dietetics programs in the United States are known as didactic programs in dietetics (DPDs) and are accredited by the Commission on Accreditation for Dietetics Education (CADE). DPDs are required to provide a curriculum that includes "foundation knowledge and skills" which are mandated by CADE for entry-level dietetic education programs.

Students who successfully complete a DPD may apply for entry into a supervised practice program. These dietetic internships, also accredited by CADE, are designed to meet the "competency statements" for the supervised practice component of entry-level dietetic education programs. Dietetic internships provide a minimum of 900 hours of supervised practice experience. Curricula for these programs include core competencies but also allow programs to train generalists or specialists in a particular practice area, such as nutrition therapy or foodservice systems management.

An alternate training route for dietitians is the Coordinated Program in Dietetics (CP). Coordinated programs provide the student with both the didactic and the supervised practice components of dietetics education in a single program. CPs may be offered in conjunction with either a bachelor's or master's degree.

After completion of both the didactic and supervised practice components of dietetics education, graduates sit for a national registration examination, which is administered under the auspices of the Commission on Dietetics Registration (CDR). Individuals who pass the examination may practice as RDs. Licensing is also required in some states; the same examination may be used for both purposes.

Dietitians who have completed their education in other countries may sit for the RD examination in the United States if their country has established reciprocity with CDR. Reciprocity requires that the course of study include both didactic and practice components. Some of the countries that have reciprocal agreements

with the United States include Canada, Denmark, and the Philippines.

The RD credential is used to protect the public from practitioners whose educational and professional credentials are below published and accepted standards. In addition, that credential must be maintained to ensure that dietetics practitioners do not allow their knowledge base to become outdated. Every five years, the RD credential must be renewed by demonstrating that a program of planned learning activities has been undertaken to allow for continued competence. Dietitians who allow their credentials to lapse must retake the registration examination in order to reestablish their level of competence.

### Dietetic Technicians

Dietetic technicians, DTRs in the United States, are dietetics practitioners who work with dietitians in all three areas of dietetics practice, clinical, foodservice, and community. They may work independently, if the expertise of a dietitian is not required for the specific task that is being done. For example, the dietetic technician could counsel a new mother on infant feeding practices but would not recommend a parenteral formula for the recipient of an organ transplant. DTRs hold at least an associate's degree and have attended a program that includes a supervised practice component.

In the United States, CADE accredits dietetic technician programs (DTs). The curriculum for these programs must include didactic content in the eight "foundation knowledge and skills." The specific requirements for DTs differ from those for DPDs in the depth involved. DTs include a supervised practice component of at least 450 hours, during which students develop the practice competencies set by CADE for DTRs.

Like RDs, DTRs are required to pass a national registration examination established by CDR. Passing the examination provides them with the credential to practice as dietetics professionals. DTRs are also required to demonstrate continued competence by engaging in planned learning activities and renewing their credential every five years.

**NUTRITION TRANSITION: WORLDWIDE DIET CHANGE.** The world is witnessing rapid shifts in diet and body composition, with resultant important changes in health profiles. In many ways, these shifts are a continuation of large-scale changes that have occurred repeatedly over time; the changes facing low- and moderate-income countries today, however, appear to be occurring very rapidly. Broad shifts in population size and its age composition; in disease patterns; and in dietary and physical-activity patterns are occurring around the world. The former two sets of dynamic shifts are termed the demographic and epidemiological transitions. Dietary and physical-activity changes, reflected in nutritional outcomes such as changes in average stature and body composition, are referred to as the nutrition transition.

### Historical Nutrition Patterns

Human diet and activity patterns and nutritional status have undergone a sequence of major shifts, which can be defined as broad patterns of food use and of corresponding nutrition-related diseases. Since the eighteenth century, the pace of dietary and activity change appears to have accelerated, albeit to varying degrees in different regions of the world. Dietary and activity changes have been paralleled by major changes in health status, as well as by major demographic and socioeconomic changes. Obesity emerges early among these shifting conditions, as does the level and age composition of morbidity and mortality. Five broad nutrition patterns have been identified, going back to the origins of modern man. The two “earlier” patterns continue to characterize certain geographic and socioeconomic subpopulations, but much of the modern world is experiencing one or more of three later patterns: receding famine; the appearance of nutrition-related noncommunicable diseases (NR–NCDs); and, in response to these, behavioral change.

**Receding famine.** In this stage, the consumption of fruits, vegetables, and animal protein increases, and starchy staples become less important in the diet. Many earlier civilizations had made great progress in reducing chronic hunger and famines, but only in the last third of the last millennium did these changes become widespread, leading to marked shifts in diet. Famines continued well into the eighteenth century in parts of Europe, however, and they remain common in some regions of the world. Activity patterns start to shift in this stage, and inactivity and leisure become a part of the lives of more people.

**Nutrition-related noncommunicable diseases (NR–NCDs).** A diet high in total fat, cholesterol, sugar, and other refined carbohydrates, and low in polyunsaturated fatty acids and fiber, and often accompanied by an increasingly sedentary life, is characteristic of most richer societies (and of increasing portions of the population in poorer societies) in this stage. These characteristics result in increased prevalence of obesity and degenerative

diseases that characterize Omran’s final epidemiological stage.

**Behavioral change.** A new pattern appears to be emerging in this stage as a result of changes in diet, evidently associated with the desire to prevent or delay degenerative diseases and prolong health. Whether these changes, instituted in some countries by consumers and prodded in others by government policy, will constitute a large-scale transition in dietary structure and body composition remains to be seen.

Nutrition science is increasingly focusing on these three later stages, in particular on the rapid shift in much of the world’s low- and moderate-income countries from the stage of receding famine to the stage of nutrition-related noncommunicable diseases. The concern about this change is so great that, for many, the term “the nutrition transition” is synonymous with it.

### Apparent Increasing Rapidity of Shifts in Dietary and Activity Patterns and Body Composition

The pace of nutrition-transition shifts from the receding-famine period to that dominated by nutrition-related noncommunicable diseases seems to be accelerating in poor and developing countries. As use of the term “nutrition” rather than “diet” suggests, the category “nutrition-related noncommunicable disease” incorporates the effects of diet, physical activity, and body composition, rather than dietary patterns and their effects alone. This usage is based partly on incomplete information, which seems to indicate that the prevalence of obesity and a number of other NR–NCDs is increasing much faster in the poor and developing world than it has in the West. Rapid growth in urban populations there is much greater than that experienced less than a century ago in the West. Another element is the shift in occupation structure and the rapid introduction of mass media.

Clearly, there are both quantitative and qualitative dimensions to these changes. On the one hand, changes toward a high-density diet with reduced complex carbohydrates and other important elements, and toward increasing inactivity, may be proceeding faster than in the past. The shift from labor-intensive occupations and physically demanding leisure activities toward less strenuous work and leisure is also occurring faster. On the other hand, qualitative dimensions related to multidimensional aspects of the diet, activity, body composition, and disease shifts may exist. For example, the human diet and every one of these other factors are composed of many components, each of which will affect a person in a range of ways. Eating meat, for instance, will provide humans with many valuable nutrients such as bioavailable iron and vitamin B<sub>12</sub> or B<sub>6</sub> not found in plant foods, but also with others such as saturated fat that, when consumed in excess, may harm human health. Social and economic stresses people face and feel as these changes occur might also be included.

At the start of the new millennium, the pace and complexity of life seem to be increasing exponentially. While the penetration and influence of modern communications, technology, and economic systems (related to what is termed “globalization”) have been a dominant theme since the late twentieth century, there seems to have been a confluence of changes in these factors that have led to a major global concern about the rapid globalization of the world economy and its impact on various subpopulations.

Increasing access to Western media and the removal of communication barriers enhanced by the World Wide Web, cable television, mobile telephone systems, and other technology are important. The accelerated introduction of Western technology into manufacturing, basic sectors of agriculture, mining, and services is also a key element.

***Globalization and China: an example.*** The types of changes the developing world is facing can be seen in considering life in China in two different periods. During the 1970s food-supply concerns still existed. There was no television, limited bus and other mass transportation, and little food trade. Minimal processed food existed, and most rural and urban occupations were very labor-intensive.

By the end of the twentieth century, work and life in China had changed. Small gas-powered tractors were available, modern industrial techniques were multiplying, offices were quite automated, soft drinks and processed foods were consumed everywhere, televisions were found in about 89 percent of households (at least a fifth of whom received Hong Kong and Western advertising and programming), younger children did not ride bicycles, and mass transit had become heavily used.

Add to such changes similar ones occurring in much of Asia, North Africa, the Middle East, Latin America, and many areas (particularly cities) in sub-Saharan Africa, and it is evident that the shift from a subsistence economy to a modern, industrialized one occurred in a span of ten to twenty years, whereas in Europe and other richer industrialized societies, it took place over many decades or centuries.

To effectively examine the nutrition aspects of these changes, one would need to compare changes in poorer countries in the period from 1980 to 2000 with changes that occurred a half century earlier in the developed world. However, data on diet and activity patterns are not available, and there is only minimal data on nutrition-related noncommunicable diseases and on obesity.

The negative elements of the nutrition transition known to be linked with nutrition-related noncommunicable diseases are obesity, adverse dietary changes (for example, shifts in the structure of diet toward a greater role for higher fat and added sugar contents, reduced fruit and

vegetable intake, reduced fiber intake, greater energy density, and greater saturated fat intake), and reduced physical activity in work and leisure. The causes of these elements are not as well understood as are the trends in each of them. In fact, there are few studies attempting to examine the causes of such changes, and there are only a few data sets that are equipped to allow such crucial policy analyses to be undertaken.

### **Obesity Trends**

The most commonly measured health outcome due to shifts in the structure of diet is obesity. Increases in overweight and obese adults in the developing world since the 1970s have occurred much faster than in richer countries. Shifts in body composition among Chinese adults have been examined (Bell et al., 2001) over an eight-year period. Not only did the average BMI (body mass index, which is the common measure for overweight status and measures weight in kilograms divided by height in square meters) level increase, but the shape of the BMI distribution curve changed over the eight-year period of the study so that there was a large proportion of high BMI adults. From 1989 to 1997 the proportion of underweight men and women dropped considerably, and the prevalence of both overweight and obesity increased greatly, the proportion of overweight or obese men more than doubling and the proportion of overweight or obese women increasing by 50 percent.

China's changes are not unique. Annual increases in the prevalence of overweight and obese adults in selected poor and middle-income countries can be compared with those in the United States. Elsewhere we present data that illustrate the annualized increases from richer countries with comparable data from poorer countries (Popkin, 2002). We also show how quickly overweight status and obesity have emerged in Mexico as a major public-health problem. Compared with the United States and European countries, where annual prevalence increases in overweight and obesity are about 0.25 percent each, rates of change are very high in Latin America. Similar shifts in the prevalence of obesity are found for North Africa and the Middle East and Asia. In each of these countries the annual rate of increase in the prevalence of overweight plus obesity is between 1 and 2.5 (Popkin, 2002).

What is important to note is that increases in the proportion of the adult population who are overweight are far greater in all of these poorer countries than in the United States or most European countries. Only Spain, with its large growth in overweight population in the last decade, is similar, in speed of change, to these countries.

### **Dietary Changes: Shift in the Overall Structure over Time**

The diets of the developing world are shifting rapidly. Good data for most countries on total energy intake are not available, but shifts in the structure of the diet can

be examined. Thus, the shift in diet, over time, in the proportion of energy derived from fat has been explored (Guo et al., 2000).

The dramatic changes in the aggregate income–fat relationship from 1962 to 1990 are found in China. Most significantly, by 1990 even poor nations (having a gross national product [GNP] of only \$750 per capita) had access to a relatively high-fat diet, which derived 20 percent of its energy from fat; in 1962 the same diet was associated with countries having a GNP of \$1,475 (both GNP values in 1993 dollars). This dramatic change arose from a major increase (from 10 to 13 percent) in the consumption of vegetable fats by poor and rich nations alike. Increases (of 3 to 6 percent) also occurred in middle- and high-income nations.

At the same time, there were decreases in the consumption of fat from animal sources for all except the low-income countries. The availability of animal fats continued to be linked to income, though less strongly in 1990 than in 1962. These decreases, combined with the increase in vegetable-fat intake for countries rich and poor, resulted in an overall decrease in fat intake for moderate-income countries of about 3 percent, but an increase of about 4 to 5 percent for low- and high-income countries.

In 1990 vegetable fats accounted for a greater proportion of dietary energy than animal fats for the poorest 75 percent of countries (all of whom had incomes below approximately \$5,800 per capita). The absolute level of vegetable-fat consumption increased, but there remained, at most, a weak association of GNP and vegetable-fat intake. Changes in vegetable-fat prices, supply, and consumption equally affected rich and poor countries, but the net impact was much greater on lower-income countries.

There has been an equally large and important shift in the proportion of energy from added sugar in the diets of lower-income countries (Drewnowski and Popkin, 1997).

Examination of the combined effect of these various shifts in the structure of rural and urban Chinese diets reveals an upward shift in the energy density of the foods consumed. Energy intake from foods and alcohol in both urban and rural Chinese adult diets increased over 10 percent between 1989 and 1997. These numbers represent a very rapid shift in energy density. (It is important to note that the Chinese Food Composition Table, from which these data were extracted, measures only a few beverages [milk, coconut juice, sugarcane juice, spirits, beer, wine, champagne, and brandy] and excludes many beverages, in particular tea and coffee, included in normal measures.) Other clinical studies have found that the consumption of higher-density diets is associated with increased total energy intake. Energy density changes in the diet of China, and most likely in other developing countries, are critical components to be monitored.

## **The Importance of Rapid Social Change, Including Urbanization, Demographic Change, and Behavioral Changes**

Diets have shifted far more dramatically in urban than in rural areas. Some critical sociodemographic issues include:

- rapid reductions in fertility that have speeded shifts in age distribution;
- unabated urbanization in Asia and Africa that will leave more of the poor residing in urban than rural areas in future decades;
- economic changes, in particular increased income and income inequality, that appear to define changes in many regions of the developing world;
- globalization of mass media that faces countries at an earlier stage of economic development than in the past.

**Urbanization.** The structure of diet has shifted markedly as populations have urbanized (Drewnowski and Popkin, 1997). This relationship will, by itself, shift the structure of national diets significantly as the proportion of the population in urban areas grows.

**Structural shifts in income-diet relationships.** Economists speak of two types of behavioral change. One relates to shifts in the “population composition” of society toward the educated, rich, or urban. The other is “behavioral” and relates to the way people with different characteristics behave, particularly their economic behavior. At the same level of education or income, a person might buy different amounts or types of commodities at different points in time. Research conducted in China shows there have been profound behavioral shifts since the 1980s. For each extra dollar of income, additional high-fat foods are being purchased, when compared with previous years (Guo et al., 2000). This suggests that the demand pattern for food has changed, so that for the same income level patterns of demand are significantly different from those in earlier periods. The explosion in access to goods and exposure to mass media may well have created this situation.

**Mass media.** There is no doubt that access to modern mass media has grown very rapidly. It is most useful to look at the proportion of households in a country that own television sets. Overall, 88.5 percent of Chinese households owned televisions in 1997. Not only the proportion of people with access to television but also the types of programs and access to Western influences were shifting. In the 1980s cable systems in China did not provide outside programming; by 1997 many provinces provided access to China Star, a Hong Kong system that relies heavily on U.S. and British programming and modern advertising.

While there are not extensive data on the proportions of Chinese households with access to mass media

more than thirty years ago, research has shown a marked increase in television ownership and viewing and indicates that media's penetration into Chinese households in 1997 is far greater than into American households fifty years ago, when television was in its infancy.

**Health effects.** The BMI-disease relationships have been found to vary between major Asian and other subpopulation groups and those of European background. Are these related to differences in the distribution of fat in a body (e.g. fat distributed around the heart and livers in the abdomen versus in the hips and buttocks), or are there underlying equally important genetic factors that account for these differences?

There are a number of different ways these questions could be answered in the affirmative. One is if body composition and other unmeasured racial and ethnic factors affect susceptibility to nutrition-related noncommunicable diseases. Another might be if previous disease patterns (such as the presence of malaria or other tropical diseases) have predisposed the population to certain problems. One component of this might be the fetal insult syndrome hypothesized and popularized by Barker.

A growing body of research shows that international standards used to delineate who is overweight and obese are not appropriate for many large subpopulations. For instance, a BMI of 25 appears to have a far greater adverse metabolic effect in an Asian adult than in a Caucasian adult (Deurenberg et al., 1998). In fact, the World Health Organization (WHO) and the International Obesity Task Force (IOTF) have formed a group of scientists and agencies in Asia to review this topic. This group has held international meetings and has proposed a lower BMI cutoff for Asians, of 23 for overweight and 25 for obesity (International Diabetes Institute, 2000). In one paper comparing China, the Philippines, and U.S. Hispanics, African Americans, and whites, the odds of being hypertensive were higher for Chinese men and women in the 23–25 BMI range than for other subpopulation groups (Bell et al., 2001). Ethnic differences in the strength of the association between BMI and disease outcomes warrant further consideration.

Zimmet and others who have focused on this issue as it relates to lower-income countries have felt that the highest genetic susceptibility for adult-onset diabetes was for Pacific Islanders, American Indians, Mexican Americans and other Hispanics, and Asian Indians. Those groups with modest genetic susceptibility include Africans, Japanese, and Chinese. The age of onset (usually after fifty) of non-insulin-dependent diabetes mellitus (NIDDM) is much lower for these susceptible populations, and it appears that the prevalence is higher for a given level of obesity and waist-hip ratio.

What is not clear is how much of this difference between subpopulations' BMI-diabetes or other BMI-morbidity relationships is a function of differences of body composition, of metabolic or genetic factors, or

of social causes. Part of the apparent race-hypertension relationship may also be explained by socioeconomic status (Bell et al., 2001).

There is possibly another factor related to the role of exposure to poor health in this population, for which there is less understanding and no real documentation of its impact (e.g., malnutrition that causes a virus to mutate, parasitic infections that affect long-term absorption patterns, or a parasite that is linked with an unknown genotype—comparable to sickle-cell anemia and its evolutionary linkage with malaria). There is no basis for speculation about the importance of this factor.

The effect of fetal and infant insults on subsequent metabolic function, however, appears to be a critical area. If rapid shifts toward obesity are occurring among those who earlier faced higher levels of low birthweight in a population, then this becomes a much more salient aspect of this argument. In the developing world, where intrauterine malnutrition rates have been and continue to remain high, and nutrition insults during infancy are highly prevalent, research suggests important potential effects on the prevalence of nutrition-related noncommunicable diseases in coming decades (Barker, 2001; Adair et al., 2001). There is an emerging consensus that fetal insults, in particular with regard to thin, low-birthweight infants who subsequently become overweight, are linked with increased risk of these diseases. Infancy itself, however, may equally be a period of high vulnerability. Three further studies by Hoffman and collaborators (2000) suggest that fat metabolism of stunted infants is impaired to the extent that it could lead to increased obesity and other metabolic shifts. Other work on the role of stunting and obesity (Popkin et al., 1996) had suggested such an effect; Hoffman's work offers the mechanism.

### **The Coming Cardiovascular Disease Epidemic**

Evidence from many developing countries shows that nutrition-related chronic diseases prematurely disable and even kill a large number of economically productive people, a preventable loss of precious human capital. Four out of five deaths from nutrition-related chronic diseases occur in middle- and low-income countries. Reddy (2002) has pointed out that these low- and middle-income countries now account for over three-quarters of global mortality and over 40 percent of the global burden of disease, measured as disability adjusted life years (DALYs) lost, that is attributable to noncommunicable diseases. Among the low- and moderate-income developing countries, the burden of cardiovascular disease alone is now far greater in India and China. Together these two countries account for over half of all new cases of diabetes in the world. Lower-income communities are especially vulnerable to nutrition-related chronic diseases, which are not only diseases of affluence. Such nutrition-related chronic diseases as cardiovascular diseases (CVDs), cancers, and diabetes are becoming major

contributors to the burden of disease, even as infections and nutritional deficiencies are receding as leading contributors to death and disability.

Furthermore, cardiovascular diseases in the developing world emerge at an earlier age. Over 45 percent of heart disease-related deaths in low- and moderate-income countries occur under the age of 70 (compared with about 20 percent in high-income countries) (Reddy, 2002).

There are large differences in the profiles of the CVD epidemic across the developing world. Hypertension and stroke, for instance, are more likely to emerge in East Asia, whereas diabetes comes earlier in South Asia.

As would be expected from the dietary and obesity data noted above, CVD levels are far greater in urban areas of the developing world; the opposite is often true in the higher-income developed countries.

### **The Social Burden of Changes in Diet, Body Composition, and Health**

In the richer countries of the world, higher-income groups increasingly follow a more healthful lifestyle when compared to poorer groups. Higher-income Americans consume a more healthful diet, exercise more, and smoke less; similar patterns are found in other high-income countries (Popkin et al., 1996). The prevailing opinion has been that the opposite is found in the developing world, namely, that the poor are less likely to have a heavy burden of nutrition-related noncommunicable diseases than the rich. This statistic is changing rapidly. Monteiro and his collaborators have shown that obesity has gone down among the better-educated, and increased among the less-well-educated, in southeastern Brazil. Soowon Kim and collaborators have shown that not only are less healthful dietary patterns common among higher-income Chinese; so are other harmful dimensions of lifestyle (inactivity, smoking, drinking). Other Chinese scholars have shown a rapid shift in food-consumption patterns among different income groups, which seems to indicate a shift in the burden of unhealthy diets toward poor Chinese (Guo et al., 2000).

### **The Future**

Consuming a more tasteful and richer diet is a goal of most of the world's population. Dietary change is universal; rapid change, though, is now seen especially in the poorest areas of the world. The challenge is to learn how to continue to improve the palatability and quality of our diet, while discovering ways to accomplish this task in a more healthful manner.

Barry M. Popkin

**NUTS.** Botanically, a nut is a hard, one-seeded fruit that is indehiscent, which means it does not split open on its own at maturity. Many commercial nuts, however, do not meet the strict botanical definition. One common characteristic of nuts is a hard outer covering or shell. The shell is a natural package that protects the inner seed, usually very high in food value, from animal predation. To overcome thick nutshells, humans (and other primates) developed tools. The most primitive tools are rocks used by chimpanzees for cracking nuts. Some scientists speculate that the shards broken from such primitive nutcrackers may have been the first scraping and cutting tools used by early humans as they gradually developed and improved technology.

Nuts may have helped spark early humans' technological creativity by coupling a challenge with a nutritious reward. The hard nutshell is a challenge that must be overcome to gain the reward of the kernel and has become a metaphor for a challenging puzzle, "a hard nut to crack." The names given to nuts by indigenous people sometimes reflect the effort of cracking. The word *pacan*, for example, was used by Native Americans to refer to all hard-shelled nuts that required an instrument

(stone or hammer) to crack. The folds, wrinkles, and lobes of walnut kernels bear a resemblance to the brain, and are similarly encased in a skull-like protective case. Under the "Doctrine of Signatures," a medical system used in the sixteenth and seventeenth centuries, that similarity was considered meaningful so walnuts were prescribed for maladies related to the head. It may be from such visual, verbal, and historical connections that the term "nut" came to be associated with the head, as well as with an idiosyncratic personality.

Modern technology has provided global access to a wide range of nut crops, at the same time threatening the maintenance of the genetic and ethnobotanical diversity that produced them. Perhaps exploring the variety of nut crops within the context of their usefulness to humanity will contribute to improved stewardship.

### Almonds (*Prunus dulcis* [Miller] D. A. Webb)

**Plant biology.** The almond is a deciduous tree of the arid temperate zone. It grows to a height of twenty-five to thirty feet and has white to pink solitary flowers, 1–1.5 inches across, that develop with or before the early foliage. The flowers of most almond cultivars are self-incompatible, although there is selection for self-compatibility, especially in Europe. Honeybees typically transfer the heavy pollen. The flower has a single pistil with two ovules. If both develop, an undesirable "double kernel" is produced. The fruit is a compressed, pubescent, oblong-ovoid drupe that splits at maturity to reveal the shallow pitted stone containing the seed (the edible kernel).

Almonds are a concentrated source of energy, being relatively high in fat (54 percent, see Table 1). The fatty acid in highest concentration is oleic acid (70–78 percent), a monounsaturated fatty acid that can contribute to lowered cholesterol levels. Kernels are also relatively

TABLE 1

Nutritive value and composition of major nut crops									
Crop	% water	% protein	% fat	fat composition			% carb	minerals	cal/g
				% sat	% oleic	% linoleic			
almond	4.70	18.59	54.23	8.05	67.01	20.00	19.51	0.48	5.98

pecans	3.40	9.19	71.15	7.00	63.00	20.00	14.58	0.97	6.86
pine nuts	3.10	13.21	61.43				20.71	0.04	6.43
pistachios	5.30	19.27	53.66	10.02	64.98	19.01	18.99	1.61	5.93
walnuts	3.50	14.78	63.94	6.99	14.98	62.00	15.79	0.93	6.50

high in protein (18 percent). Seedlings vary in kernel quality, with some producing bitter kernels due to high levels of the glucoside amygdalin. Amygdalin is hydrolyzed by the enzyme emulsin to form benzaldehyde and cyanide, which cause the bitter taste. Substrate and enzyme are both present in the seed and are united when cells are injured, as occurs during consumption. The trait has adaptive value as a protection against predation.

**History.** Almonds originated in Asia and moved with the migrations of peoples, which were often impelled by the upheavals of famine and warfare. In Genesis 43:11, the patriarch Jacob instructed his sons to carry almonds and pistachio nuts from their home in Palestine to Egypt when the family had to relocate during a period of extreme famine (c. nineteenth century B.C.E.).

The almond may have been introduced in Greece during the conquests of Alexander the Great (c.320 B.C.E.). From Greece, almonds spread into Italy and the Mediterranean region, a movement that can be traced in the etymology of the English word. "Almond" is derived from the French *amande*, from the Latin *amygdala*, which came from the Greek.

The Arab conquest of North Africa in the sixth and seventh centuries started another wave of almond introductions. The Moors took almonds with them when they conquered southern Spain. Almonds were then transported from Spain to California during the Spanish Mission Period (1800). The warm, dry climate of California, coupled with intensive agricultural systems, led to the preeminence of California in world almond production.

Almonds are currently grown in regions characterized by a subtropical Mediterranean climate. Primary production centers are the central valleys of California, the Mediterranean region, and Central to Southwestern Asia.

**Procurement.** In California, culture is intensive. Cultivars are selected for high production of soft-shelled kernels. Grafted trees of improved cultivars are propagated on rootstocks selected for the constraints of particular sites. Trees are planted in irrigated orchard configurations with densities of up to 134 per acre. Two rows of the main cultivar to one row of a pollinizer are planted and hives of bees are maintained to aid pollination. Trees are heavily fertilized and protected with chemical pesticides, and yields of over 3,000 pounds of kernels per acre are achieved. Harvest operations are heavily mechanized, with specialized machines to shake nuts from the tree and others to collect them from the orchard floor.

In the Mediterranean region of production, culture is not as intensive, and many orchards are composed of selected seedlings rather than grafted trees. Furthermore, most classes and cultivars are hard- or semi-hard-shelled. Orchards contain fewer trees than in California, with only fifty to seventy trees per acre being typical. Selection has occurred within particular regions that have become

identifiable for the class of almonds produced, despite heterogeneity. For instance, the Spanish island Majorca is known for the Farmer Majorca class, composed of a multitude of related seedling trees. Recent selection has been for late-blooming cultivars that avoid frost damage, for self-compatibility, and for adaptation to the environmental stresses that are not as completely controlled as in California.

**Global and contemporary issues.** Standardization accompanying globalization puts pressure on diversity. Increased uniformity allows increased mechanization, and may contribute to marketability and even profitability, but at the cost of genetic diversity. Small areas in the Mediterranean once comprised distinct land races of selected seedlings. The diversity of those local populations is being reduced as grafted culture increases. Maintenance of ex situ germ plasm collections cannot substitute for the continued selection of desirable seedlings by multiple local growers.

### **Brazil Nuts (*Bertholletia excelsa* Humbl. & Bonpl.)**

**Plant biology.** Brazil nuts are produced by giant evergreen trees indigenous to the Amazon forest of South America. Trees may reach heights of over 160 feet, and form part of the upper forest canopy. Cream-colored flowers are borne in racemes at the ends of shoots, and have both male and female parts. Female *Euglossine* bees accomplish pollination, while males of that species primarily visit orchids. Flowers mature and drop quickly, within a single day. Fruit matures in fourteen months, falling from the tree from January to June. The fruit is a four- to six-inch spherical pod with a thick outer shell encasing twelve to twenty-four wedge-shaped nuts, each in its own dark brown rough shell. Each nut is two inches long or more and has a single solid kernel. Kernels are about 66 percent fat, 20 percent of which is saturated (see Table 1). The high oil content makes the nuts valuable as a source of oil for cosmetics and soap making, as well as for consumption. The nuts are about 14 percent protein and are a concentrated source of selenium, which is being studied for its role in preventing some forms of cancer.

**History.** Although Brazil nuts have been used by indigenous people of the Amazon for millennia, they were "discovered" by the outside world in 1569 when Juan Alvarez Maldonado was directed to the nuts by the Cayanpuxes Indians on the Madre de Dios River. The Spanish called the nuts "almendras de los Andes" or "almonds of the Andes." Dutch merchants began trading for Brazil nuts in the early 1600s, but it was not until the beginning of the nineteenth century that the tree was given its botanical name. The German botanist Alexander von Humboldt and his French colleague Aime Bonpland went on an expedition to Brazil in 1799; following their return to Paris about five years later, the men named the nut after von Humboldt's friend Claude Louis Berthollet.

Brazil nuts became a traditional Christmas delicacy in England in the nineteenth century, and the market for the nuts soared as rubber exports increased in the last half of the century: the settlers who ventured into the forest to harvest rubber also harvested the Brazil nuts. When the market for rubber dropped, the demand for Brazil nuts remained consistent and has continued to support the *castaneros* who make their living harvesting the wild trees. The value of the nuts is dependable enough to serve as a type of currency in the area where they are grown.

**Procurement.** Brazil nuts are the only globally distributed nut crop produced almost entirely from wild trees. The long time required to establish a bearing tree, and low yields related to problems with pollination in established orchards, have made plantations of the trees economically unattractive. Most nuts come from the Brazilian states of Para, Amazonas, and Acre. Brazil nuts are also produced in Bolivia, Peru, Colombia, the Guianas, and Venezuela. A single tree may produce over 300 of the heavy, nut-filled pods. *Castaneros* do not stand under the trees in windy conditions to avoid being hit and possibly killed by the falling pods. Most collecting is done in the morning, and an experienced worker can collect close to a thousand pods in a day. Pods are opened with a machete, and nuts are carried to the river in sacks often weighing over one hundred pounds. They are taken by canoe or raft to marketing centers, where a few exporters accumulate and market the crop and receive the majority of the profit.

**Global and contemporary issues.** Increased attention has focused on Brazil nuts as a “keystone species,” a species critical to the intricately interwoven web of life for many organisms. Studies in the wild have revealed the role of specialized bees for pollination, a factor that may be missing in planted orchards. The agouti, a large rodent, is unique in its ability to open the pods and to scatter-hoard the nuts, contributing to seedling establishment. Other organisms rely on the empty pods as a substrate for development. In recognition of their value to local people, laws in several countries prevent cutting down Brazil nut trees. Creative efforts are being made by local people to market the valuable crop directly and establish a sustainable ecological and economic system centered on this valuable nut tree.

### Cashew Nuts (*Anacardium occidentale* L.)

**Plant biology.** The cashew tree is a medium-sized (up to forty feet tall), spreading evergreen tree that originated on the dry, salty coastal beaches of northeast Brazil. Trees have a deep taproot and extensive lateral roots that adapt them to their habitat. Leaves are simple and alternate, with entire margins. Flowers may be unisexual or perfect and are borne in terminal-branching panicles. The fruit is composed of a greatly enlarged receptacle, sometimes called the “cashew apple,” at the base of which develops a thick-shelled, single-seeded, kidney-shaped nut. Inside

the nut is the edible kernel, covered with another, thinner shell. Between the outer and inner shells is a thick, caustic oil called “cardol” that can cause blisters and must be removed. The kernels are roasted to remove toxins. Cashews are lower in oil than many nuts, having only 45 percent. The primary oil is oleic acid. Kernels are relatively high in carbohydrates (see Table 1). In addition to the edible nuts, the peduncle (or apple) can be eaten, pressed for juice, or used to make wine. The caustic nut-shell liquid (CNSL) has heat-absorbing properties that make it useful in several industrial applications, from clutch facings to waterproof paints. Other plant parts are also useful: sap is used as insect repellent and varnish, and leaves and bark are used medicinally.

**History.** Indigenous people of Brazil were using cashew nuts and apples when the first Europeans visited in the mid-1500s. The Portuguese introduced trees to India in the 1560s, from which the species spread to other tropical parts of Asia. India was the source of the first international trade in cashews in 1907, exporting 430 tons of kernels to Britain and importing unshelled nuts from East Africa.

**Procurement.** The World Bank estimates that 97 percent of world cashew production is from “wild trees” (self-sown rather than systematically planted in orchards), although research on crop improvement is proceeding in Brazil, India, and Africa. Seedlings are capable of producing nuts only three years after planting. The vast majority of the very perishable cashew apples are allowed to rot rather than being processed. Yield from a mature cashew tree is estimated at between 100 and 150 pounds of fruit (apples and nuts), from which twenty pounds of hulled, unshelled nuts can be obtained, yielding about six pounds of kernels. Nuts are dried immediately after harvest, and then must be roasted to remove the caustic nut-shell liquid, which complicates processing. Traditional methods of roasting result in the loss of the CNSL, as well as causing hazardous working conditions due to spurting oils and toxic smoke. More modern extraction methods salvage the CNSL, but require expensive solvents and technical expertise.

### Chestnuts (*Castanea* spp.)

**Plant biology.** Chestnuts are deciduous trees with simple, alternate leaves that have serrate to dentate margins. Chestnuts are monoecious, with separate male and female flowers on the same tree. Male flowers are borne as unisexual catkins at the terminal end of shoots and as bisexual catkins on the lower shoots. Female flowers appear singly or in clusters of two or three at the base of the bisexual catkins and become the nut-bearing burrs. Male flowers tend to shed pollen prior to female receptivity, creating a tendency to cross-pollination. Pollen is primarily wind disseminated. The fruit is a spiny burr that dehisces into four valves at maturity to reveal three nuts. Chestnuts are rich reddish brown with a conspicuous pale

oval scar at the base. The shell is relatively thin and is not as protective as the burr is. When the shell is removed, a hairy pellicle (seed coat) covers the embryo and two irregular cotyledons. Chestnuts have the highest water content, the lowest fat content, and the highest carbohydrate (starch) content of any nut crop (see Table 1). If chestnuts dry after harvesting, some of the starch converts to sugar and viability of the seed is lost. As a result, post-harvest handling dramatically affects both the edible quality of the product as well as its viability for seed.

Three species account for the majority of world production: the Chinese chestnut (*Castanea mollissima* [Bl.]), the European chestnut (*C. sativa* [Mill.]), and the Japanese chestnut (*C. crenata* [Sieb & Zucc.]). All species have a somatic chromosome number of  $2n=24$  and hybridize freely.

**History.** Seven species of *Castanea* are found around the world in the temperate zone, and each has a long history of utilization. The Japanese chestnut is native to the Japanese islands and Korea and has been cultivated for over 2,000 years, with some cultivars being maintained since 750 C.E. The species is considered the most domesticated, with the largest fruit, the most precocious seedlings, and the smallest mature tree size. Unfortunately, some of them produce nuts that are not very palatable until they have been cooked.

Most chestnuts consumed in Europe and the United States are derived from the European chestnut, which has been cultivated in southern Europe and Asia Minor since the Roman Empire. Increasingly, hybrids between the European and Japanese chestnuts are grown commercially because the latter species is resistant to ink disease.

American chestnuts (*C. dentata* [Marsh.] Borkh) were a dominant tree in the eastern forests of North America until ink disease (*Phytophthora cinnamomi*) eliminated them from the Gulf states in the early 1800s, and chestnut blight disease (*Cryphonectria parasitica* [Murr.] Barr) developed in the United States in the late 1800s. Ink disease probably came in on cork oak trees from Portugal, which were planted in the south before 1823. Blight disease was introduced in the 1880s, with Japanese chestnut planting stock. It spread up and down the eastern seaboard with nursery stock, and then moved into the forest by other vectors, until by 1950 almost all large chestnut trees were infected. Ink disease is lethal to chestnuts, but the blight fungus does not kill roots, so trees continue to sprout, are reinfected, and die back. There is good evidence that, in the southern United States, heavy shading, competition, grazing, and continued infections often kill the trees completely, but this is not the case in northern forests, where canopy type, competition, and predation are quite different.

In addition to the two diseases, chestnuts in the United States are also threatened by the Oriental Chestnut Gall Wasp (*Dryocosmus kuriphilus*), another introduced pest that has become established and is damaging

native chestnut species. The Gall Wasp is believed to have been introduced from Asia into Georgia in 1974 on scion wood that did not pass through proper quarantine. It infested orchards of Chinese chestnuts in Georgia and has also been found in wild trees of the American chestnut along the Appalachian Trail.

**Procurement.** Chestnuts are exported in large numbers from Italy, Spain, Australia, China, and Korea. Japan and the United States are primarily importers, although these markets are partially satisfied by locally grown chestnuts. New cultivars are being registered at an increasing rate, and interest in the crop is increasing.

**Global and contemporary issues.** The chestnut exemplifies both the dangers and benefits of globalization. The devastation of the North American forest by introduced diseases and insects argues in favor of the careful regulation of genetic materials moving between countries. Breeding programs are succeeding in developing resistance to these pests by the use of interspecific hybrids that were created using introduced germ plasm, illustrating the value of carefully sharing genetic resources.

### Coconut (*Cocos nucifera* L.)

**Plant biology.** The coconut is a tall, tropical palm tree that reaches reproductive maturity six to ten years from planting and may live one hundred years. Tall varieties may reach heights of one hundred feet and have a single, usually curved or leaning, trunk with smooth gray bark marked by the ringed scars left by fallen leaf bases. A many-leafed crown tops the trunk, with each pinnately compound leaf being fifteen to twenty feet long. Male and female flowers are borne on a fleshy spike (spadix) enclosed within a leaflike sheath (spathe) arising from the leaf axils. Female flowers are in the basal position and male flowers are at the apex. Pollination may be either anemophilous (wind-distributed) or entomophilous (insect-distributed). The fruit is a large drupe eight to nine inches in diameter. The coconut has a thin, smooth, grayish brown epicarp, a one-to-three-inch-thick, fibrous mesocarp (yielding coir, a fiber used in thatching), and a woody endocarp (the shell). Inside the shell the endosperm comprises the single seed. A portion of the endosperm is solid (the flesh) and a portion is liquid (the milk). The coconut is light in relation to its volume, which allows it to float and be transported by water for long distances. Eventually it washes up on sandy, saline, tropical beaches where it is well adapted to survive. When the embryo germinates, the radicle emerges through one of three germinating pores visible on the outside of the shell. The three pores give the head-sized coconut the appearance of a monkey face. The genus name *Cocos* is derived from the Portuguese word for "monkey."

Coconut oil is extracted from the dried flesh, or copra, and is rich in lauric acid, a valuable antifungal, antiviral, and antiprotozoal compound. As a food, coconut oil is very high (86 percent) in saturated fats, which oc-

cur as medium-chain triglycerides that do not raise serum cholesterol or contribute to heart disease as much as long-chain triglycerides. Coconut oil is also a component of soaps and other health products.

**History.** Coconut fossils from the Tertiary period have been found in the Indo-Pacific Ocean region where the plant originated, and charred coconuts have been found in Western Melanesian archeological sites dated to 3000 B.C.E. The plant is a valuable source of food (the flesh), drink (the milk), and shelter (leaves, shell fibers, and trunk). In Sanskrit, the coconut palm is called “the tree which provides all the necessities of life.” As a valued source of life’s requirements, the coconut was spread by seafaring people throughout the Pacific, possibly as far as the Pacific coast of Central America, and west to India and East Africa. The first written mention of the tree was by an Egyptian monk in 545 C.E., and Marco Polo described coconuts growing in Sumatra, India, in 1280 C.E.

**Procurement.** Coconuts were first established in large-scale commercial plantations in the mid-nineteenth century, many from the seeds of local wild palms along the seashore. Planted coconuts now greatly outnumber wild palms, and coconut products form the main export of Ceylon, the Philippines, and other Indian and Pacific Ocean islands.

### Hazelnuts (*Corylus avellana* L.)

**Plant biology.** Hazelnuts, also known as filberts, are produced on small, shrubby, often multitrunked trees that usually grow to heights of fifteen to twenty-four feet. They have simple, alternate, round-oval leaves with toothed margins. Hazelnuts are monoecious, with both male and female flowers on the same plant, but they are not self-fruitful. Flowers appear before the leaves. Male flowers are borne in catkins at nodes on one-year-old wood, and their wind-disseminated pollen is shed in mid-winter. Female flowers are inconspicuous clusters of tiny flowers enclosed within bud scales, visible at the time of pollination as bright red stigmas extending from buds. Fruit matures from early September to October, with the ovoid or oblong nut inside a leafy husk. There is wide diversity in fruit and husk shape, and that diversity is reflected in the common names: “hazel” is from the Old English word for hood or bonnet (*hæsel*), which referred to a nut whose husk was shorter than the nut. “Filbert” is probably derived from the name of St. Philibert, a Frankish abbot whose feast day falls in the season when the nuts ripen; it has also been said that the name comes from “full beard,” which referred to a long husk. In some countries long nuts are called “filberts,” while shorter, round nuts are called “hazels.”

The nuts are composed of a shell that has variable amounts of pubescence, especially at the tip. Inside the shell, the kernel is encased in a more-or-less-fibrous seed coat (pellicle) that is usually removed by blanching. Kernels are high in fat (62 percent), with the predominant

being oleic acid (see Table 1). Hazelnut kernels are also high in Vitamin E, averaging 400 mg/100 g.

**History.** The European hazelnut was the first plant of the temperate deciduous forest to move into areas vacated by receding glaciers at the close of the last ice age, due primarily to its great climatic tolerance. Nuts are recovered at European archeological sites in conjunction with prehistoric human settlements, indicating a long history of food usage. Hazelnuts are one of Europe’s oldest cultivated plants. They have been grown for centuries in Turkey, Italy, Spain, France, Germany, and England, although different conventions have arisen for their culture in each country. Hazelnuts were introduced in North America by shipments of seed sent in 1629 to the Massachusetts Company. Due to the eastern filbert blight (*Anisogramma anomala* [Peck] E. Muller), the culture of hazelnuts in the United States is concentrated in the coastal valleys of Oregon and Washington.

**Procurement.** In Turkey, the leader in world hazelnut production (65 percent), hazelnuts are cultured in traditional systems that rely on hand labor. Multitrunk seedling trees are planted in clumps of four or five bushes, often arranged irregularly on steep hillsides. Stems are progressively removed as they grow too old, allowing younger shoots to come into production. Nuts in the husk are hand harvested before the crop drops.

Italy follows Turkey in hazelnut production, accounting for about 23 percent of world production. Hazelnut culture in Italy is similar to that in Turkey, using clumps of multitrunk seedling trees, but with more uniform spacing. In Spain, where about 5 percent of world production originates, orchards are planted in still more regular rows, with a single bush at each location rather than a clump of separate bushes as in Turkey and Italy.

The United States produces about 3 percent of the world hazelnuts. In the United States, hazelnuts are grown in systems that facilitate mechanization and maximize nut size and yield per acre. Grafted trees of selected cultivars (mostly “Barcelona”) are grown as single-trunk trees in evenly spaced rows, with about 200 trees per acre. Trees are sprayed with chemicals to accelerate and concentrate ripening. Nuts fall to the ground and are mechanically windrowed and harvested.

**Global and contemporary issues.** The European hazelnut, *Corylus avellana*, hybridizes with other species of *Corylus* that occur from China to the United States and that are largely untapped resources. The genetic diversity of the European hazelnut is well established, based on diverse seedling culture in the primary production centers. The potential is excellent for continued genetic improvement of hazelnuts through selection and breeding.

### Peanuts (*Arachis hypogaea* L.)

**Plant biology.** The peanut (or groundnut) probably originated in South America although it was also cultivated in

ancient China. It is a low-growing annual legume with subterranean fruits. Its leaves are stipulate and even-pinnate, mostly with two pairs of oval leaflets and no tendrils. Flowers are formed in the axils of leaves and have a very long pedicel. Flowers are self-pollinated and usually do not open. After pollination, cell division in the pedicel drives the pod below ground, where it ripens. The fruit is an indehiscent, fibrous, constricted pod containing one to three dry edible seeds, each encased in a papery integument. The seeds are 20 to 25 percent carbohydrate, 25 to 30 percent protein, and 45 to 50 percent oil (see Table 1).

**History.** Peanuts may have been domesticated by selection from the related species *Arachis monticola*, found in northwest Argentina, and the only other member of the genus with the same chromosome number ( $4x = 40$ ), although other candidates are possible. Peanuts have been found in archeological sites in Peruvian desert oases dated to 2000 B.C.E. and were mentioned in Spanish historical records in 1550. Four major varieties of peanut form the foundations of world trade. “Virginia” prostrate peanuts were reported in the West Indies by the Spanish, and introduced from there into Mexico, as well as to West Africa via slaving ships. This variety was introduced to eastern North America from both the West Indies and West Africa in the seventeenth century. The Spanish took “Peruvian” prostrate peanuts from Peru to the Philippines and into southeastern China before 1600, with subsequent transport by Chinese traders. “Spanish” peanuts are an erect variety that is very high in oil. They were taken from Brazil to Africa in early introductions, and were established in Spain in the late eighteenth century. From Spain the “Spanish” peanuts were taken to southern France and were introduced in the United States in 1871. The “Valencia” was named for a location in Spain and introduced in the United States from that region about 1910. However, it had been introduced in Spain from Cordoba, Argentina, about 1900.

**Procurement.** Peanuts are grown worldwide in areas that have hot summers, alternating wet and dry seasons, and sandy soils. The plant is capable of fixing nitrogen in root nodules via symbiosis with the *Rhizobium* bacterium. Plants are harvested by digging and are piled to dry. In the United States, yields of over two tons per acre are often achieved. The major world producers of peanuts are China, India, and the United States (USDA–National Agricultural Statistics Service, 2001). The primary use for peanuts is as a source of edible oil, but they are also eaten as a food either boiled or dried. The tops of plants, as well as the residual protein-rich cake from oil extraction, can be fed to cattle.

### **Pecans (*Carya illinoensis* [Wangenh.] K. Koch)**

**Plant biology.** The pecan is a deciduous, temperate tree species native to North America. It is found in well-drained alluvial soils of the Mississippi River and its trib-

utaries from Illinois and Iowa south to the Gulf Coast of Louisiana and west to the Edwards Plateau of Texas. Isolated populations are found as far east as southwestern Ohio, as far west as Chihuahua, Mexico, and as far south as Oaxaca, Mexico. In modern times, the distribution of pecans has been extended from the Atlantic seaboard west to California, with major commercial production in the non-native states of Georgia and New Mexico.

Trees are long-lived (to 300 years) and grow to heights of over 120 feet. Leaves are alternate, odd-pinnately compound, with nine to fifteen serrate leaflets. Trees are monoecious (male and female flowers are borne on the same tree) and dichogamous (male and female flowers mature at different times), a system that encourages out-crossing with other trees of a complementary bloom period. Male flowers are borne on pairs of three stalked catkins that arise from buds of the previous season. Female flowers are borne as spikes at the tip of the current season’s shoots, usually with two to four flowers per spike. Pollen is disseminated by wind (anemophily). The fruit is a “drupelike nut,” with the dehiscent husk splitting at maturity (usually September to December) to expose the elongated, relatively thin-shelled nut. Kernels are two-lobed, separated in the shell by an internal partition or septum. Kernels are high in oil (70 percent), with the predominant oil being oleic acid (60 to 70 percent).

**History.** Some scientists think that early people carried pecan nuts north as the Laurentide ice sheet retreated at the close of the last ice age. Nuts have been found in Illinois in association with the artifacts of early people dated to around 8900 B.C.E. There is a rich history of pecan use by Native American tribes recorded in the writings of Hernando de Soto, Cabeza de Vaca, and Oviedo. Dense groves of native pecan trees growing along the Guadalupe River of Texas were visited every other year, due to the alternate-bearing cycle. In years of heavy production, pecans were a major component of people’s diet.

Shell thickness and nut size were probably the two most important criteria of selection by early foragers, just as they are for modern pecan collectors. Trees producing large, thin-shelled nuts are more highly valued, more regularly visited, more extensively harvested, and (probably) more widely dispersed over time. About 1882, Edwin E. Risien of San Saba, Texas, offered a prize for the best native pecan. His intention was to obtain nuts from the prize-winning tree and plant them to establish an orchard of superior seedlings. The tree that won the competition came to be known as the “San Saba” pecan. Seedlings of that tree were selected and propagated, producing the “Western,” “San Saba Improved,” and “Onliwon” pecans, among others.

The first report of successful asexual propagation was by Abner Landrum in 1822. However, it was the gardener Antoine, a slave, who first established a commercially viable orchard by asexual propagation by grafting “Centennial” pecan on the Oak Alley Plantation in

Nuts have always provided a dimension of humor in cookery. From left to right: Folk art serving basket for walnuts constructed of sliced walnut shells and wire, American circa 1870. Cast-iron nutcracker in the form of a dog, American, circa 1930 (press the tail and crack the nut). Austrian marzipan mold of carved boxwood, circa 1840. Marzipan (almond paste) is used here to make faux walnuts and walnut shells. ROUGHWOOD COLLECTION. PHOTO CHEW & COMPANY.

Louisiana in 1846. In the late 1800s several nurseries sold grafted trees, providing material for the first great boom in pecan orchard establishment, which occurred in Georgia in the early 1900s. The extensive acreage established at that time, largely using the “Stuart” cultivar, quickly moved Georgia to the lead in production of improved pecans.

**Procurement.** Native pecans are harvested from wild trees. Trees are often unmanaged except at harvest and yield less per acre and have lower-quality pecans than improved orchards. As a result, native pecans sell for less on the market. Land clearing for other crops greatly reduced native pecans during the last quarter of the twentieth century. Efforts to characterize and conserve the diversity of native pecans are being pursued.

Commercial pecans are grown in orchards of variable numbers of selected cultivars, grafted onto regionally adapted seedling rootstocks, in configurations that vary by geographic region. Tree density tends to increase from the East to the West, with many orchards planted on 50' × 50' spacings in the East, with 35' × 35' spacings common in Texas, and 30' × 30' spacing common in New Mexico and farther west. Cultivar diversity tends to be greatest in the Southeast, while many western orchards contain large blocks of a single cultivar, usually “Western.” Grafted trees begin to bear between the

fourth to eighth leaf, but may not achieve a positive cash flow until the twelfth to fifteenth leaf. Cost of culture varies by region, with increased cost for pesticide application in the Southeast, but increased irrigation expense in the arid West.

Pecans are the most important nut crop in Mexico, which has native as well as grafted orchards. Pecans are also grown to some extent in Israel, South Africa, Australia, Egypt, Peru, Argentina, Brazil, and China.

**Global and contemporary issues.** The United States is the world center of diversity for the pecan. As native trees are cleared, much of that diversity may be lost. Efforts are being made to collect and characterize the diversity of the pecan across its range and to establish appropriate in situ reserves.

### Pine Nuts (*Pinus cembroides* Zucc.)

**Plant biology.** Pine nuts are produced by the *piñon* pine tree, a small- to medium-sized tree found at high elevations in the arid North American Southwest. *Piñon* is found from west Texas to California, north to Wyoming, and south into Chihuahua, Baja California, and Hidalgo, Mexico. Trees form broad pyramidal crowns and become round-topped with age. Trunks are often twisted and gnarled, with rough, irregularly furrowed bark. Typically

there are two needles per fascicle, with needles being one to two inches long, sharp-pointed, and fragrant. Trees are monoecious, with male flowers produced as short staminate cones. Female cones are lateral or subterminal, about one to two inches long and almost as wide, and brown at maturity. Cones mature the second year, in August to September. The brown to black edible seeds are one-half to three-quarters of an inch long, triangular to ovate in shape, and often rounded at the base. They have a thin, brittle shell. The kernels are aromatic and flavorful, are rich in fat (61 percent), and have about 13 percent protein (see Table 1).

**History.** Pine nuts have been found in excavations at Gatecliff Shelter, Nevada, and dated at 6,000 years B.C.E. Nuts were used by Native Americans in the Southwest as an important component of their diet, both medicinally and ritualistically. The terminal buds, inner bark, and the core of green cones can be eaten in the spring. Several parts of the plant were used medicinally: crushed nuts for treatment of burns; pitch for treatment of wounds; smoke from burning branches for treatment of coughs, colds, and rheumatism; fumes of burning pitch for head colds, coughs, and earaches. Wood was used as fuel and in construction. Pitch was used for waterproofing, as a black dye, and as an adhesive. Ritualistically, the pitch was used by the Navajo to prepare corpses for burial, and by the Hopi, who painted it on their foreheads to protect them from sorcery.

**Procurement.** Most nuts are harvested from wild trees when the crop presents itself, which is irregularly. Traditionally, nuts are collected from the ground after the cones have opened. Piñon nuts have become regionally popular as an ingredient in specialty recipes, and the demand for nuts has been met by harvest practices that damage the tree, such as breaking off cone-bearing limbs. Once harvested, nuts store well and may be kept for up to three years without becoming rancid.

### **Pistachios (*Pistacia vera* L.)**

**Plant biology.** Pistachios are members of the same family as the cashew nut, the Anacardiaceae (which also includes mango and poison ivy). Commercial pistachio nuts are produced by *Pistacia vera*, a deciduous tree that grows to a height of twenty-five to thirty feet, with alternate, pinnately compound leaves, each with three to five leaflets. Trees are dioecious, producing male flowers on some trees and female flowers on others. Both male and female flowers are borne on panicles in the axils of the previous year's growth. Pollen is spread by the wind to the apetalous female flowers. The fruit is a dry drupe with an outer hull and a dry, thin shell that splits upon drying to expose the greenish kernels, each usually about one inch long by one-half inch wide. Kernels have about 20 percent protein and over 50 percent fat, 65 percent of which is the monounsaturated fat oleic acid.

**History.** The pistachio tree probably originated in western Asia and Asia Minor, but grows wild eastward to Pakistan and India. Pistachios have been recovered from archeological excavations in Jordan, dated to 6760 B.C.E. The Jewish patriarch Jacob instructed his sons to carry pistachio nuts and almonds with them from their home in Palestine to Egypt, as gifts for their brother Joseph, when the family had to move during a period of extreme famine (*New International Version Study Bible*, Genesis 43:11). Pliny reported that pistachios were introduced to Italy from Syria during the first century B.C.E., and spread from there throughout the Mediterranean area.

Pistachios were first introduced to the United States around 1853–1854 by the commissioner of patents, who distributed seed for experimental purposes. The crop did not gain much interest until later introductions began to fruit, in about 1881. The cultivar “Kerman” was introduced in Chico, California, by USDA (United States Department of Agriculture) plant explorer W. E. Whitehouse in 1929, from collections made near Kerman, Iran. That cultivar is the basis of the California pistachio industry.

**Procurement.** The major pistachio-producing areas are Iran, Turkey, and the San Joaquin Valley of California. In Iran and Turkey, nuts are harvested from trees of improved cultivars growing in established orchards, but harvesting and processing methods are primitive. Nuts are harvested by hand and many are allowed to dry in the hull, which can stain portions of the shell red, making them unattractive. As a result, many imported nuts are dyed with a red vegetable dye to camouflage the stains. Pistachios produced in California are mechanically harvested, hulled, and dried, and are unstained. Technology ensures that they can usually be marketed in natural condition. Small, wild nuts with desirable green color are still harvested in Afghanistan, although destruction of forests by clearing, overgrazing, and producing charcoal has reduced wild populations.

**Global and contemporary issues.** International political issues have resulted in barriers to marketing pistachios, which has influenced domestic crop value and acreage planted.

### **Walnuts (*Juglans regia* L.)**

**Plant biology.** Nuts from several species of the genus *Juglans* are consumed worldwide, but the most horticulturally important is the Persian walnut. Persian walnut trees grow to heights of seventy-five feet and have trunks with tight, silvery bark. Shoots have chambered pith, distinguishing *Juglans* from its sister genus *Carya* (which has a solid pith). Leaves are odd pinnately compound, with five to nine elliptic-ovate to long elliptic leaflets with entire margins, while black walnuts have more leaflets (fifteen to nineteen) that have serrate margins. Male flowers are borne laterally as single catkins on shoots of the previous season. Female flowers are borne terminally on current season shoots and usually have one to three nuts.

Flowers are wind pollinated, and male and female flowers mature at different times of the season, promoting cross-pollination, which results in increased heterozygosity. Despite the predisposition to cross-pollinate, walnuts are self-fruitful. The fruit is a drupelike nut with a thick, irregularly dehiscent husk covering a shallowly fissured shell that encases the two kernels, each of which is deeply divided at the base.

Walnut kernels are rich in oils (64 percent), making them a high-energy food. The primary fatty acid is linoleic (62 percent), a polyunsaturated oil (see Table 1).

**History.** Progenitor trees were originally distributed across mountainous regions of central Asia, from eastern Turkey to Xin-jiang Province of western China. Walnuts have a long association with humans and have been found in archeological excavations of caves inhabited by prehistoric groups in China and the United States. Initial selection for large nut size and thin shell could have been unconscious, as seeds from unconsumed caches of preferred seed germinated and established seedlings near habitations. Over time, and in association with people, walnuts having large, relatively thin-shelled nuts were developed.

Improved walnuts were sent to Greece from Persia “by the kings,” according to the Roman historian Pliny. From Greece, walnuts were introduced to Rome, where they were given the Latin name *Jovis glans* (‘nut of Jupiter’), which was contracted to provide the genus name *Juglans*. The connection to Persian royalty is reflected in the specific epithet *regia*, meaning ‘royal’. Romans spread walnuts throughout the Mediterranean, where the trees readily adapted to the warm, dry climate. The trees spread across Europe and into England where they became known in Old English as *wealhbnutu* (*wealhb* means ‘foreign’ or ‘strange’, and *bnutu* means ‘nut’). Although the tree is not capable of bearing profitable crops in the cool, wet English climate, it was esteemed for its high-quality wood. Walnuts were carried around the world in English ships, and came to be known in commerce as “English walnuts.” Walnuts came to the United States with the first settlers in New England, although the first established production was from Spanish materials introduced in California.

**Procurement.** Walnuts are intensively cultured in California, with improved cultivars selected for high production and quality grafted onto hybrid rootstocks. Pollinizer cultivars are included to provide adequate cross-pollination. Orchards are irrigated, with up to five acre-feet of water per acre being required to mature a crop. Trees are chemically protected from pests, and mechanically harvested and processed.

In Europe and Asia, much production comes from seedling trees, with use of grafted cultivars increasing in Western Europe. Over centuries of cultivation, the selection of horticulturally valuable individuals and continued propagation by seed have resulted in distinct landraces in different regions.

**Global and contemporary issues.** In Europe, the economic incentive to increase production and quality by establishing monocultures of a few genotypes is being balanced by the awareness that regionally distinct land races provide a valuable source of genetic diversity. As more seedling trees are harvested for their valuable lumber, the need for conservation by in situ reserves has increased.

**OBESITY.** Obesity and overweight now affect more than 50 percent of adult Americans. Diabetes mellitus, hypertension, heart disease, gallbladder disease, and some forms of cancer result from obesity. Whether these diseases are yet present or not, the obese individual should be encouraged to lose weight by appropriate methods to reduce the future likelihood that they will develop. Methods of weight loss include diet, nutritional education, self-help groups, and behavioral change. Under some circumstances drugs or surgery may be considered.

#### Definition and Measurement of Obesity

Obesity and overweight are best defined using the body mass index (BMI). This index is determined by dividing body weight in kilograms by the square of the height in meters:  $BMI = W/H^2$ . The normal rate for BMI is 18.5 to 25. A BMI between 25 and  $30 \text{ kg/m}^2$  is defined as overweight and a BMI above  $30 \text{ kg/m}^2$  is defined as obesity (Table 1). Visceral fat can be used as an index of central adiposity. An increase in visceral fat reflects central obesity and increases health risks. The waist circumference is used to assess the amount of visceral obesity. A waist circumference in men of 40 inches (102 cm) or more, and

in women, of 35 inches (88 cm) or more, is the threshold for defining central obesity (Table 1).

#### Prevalence of Overweight

More females than males are overweight at any age. The frequency of overweight increases with age to reach a peak at forty-five to fifty-four years in men and at age fifty-five to sixty-four in women. The National Health and Nutrition Examination Survey (NHANES) conducted by the U.S. government (published in 1993) found a BMI of 25 or more in 59.4 percent of men age twenty years or older and in 50.7 percent of women over the age of twenty years. The prevalence of obesity (BMI 30 or more) was 19.5 percent in men and 25.0 percent in women. The incidence of obesity continues to increase dramatically in the United States and elsewhere. A number of factors including age, sex, and physical inactivity influence the amount of body fat.

At birth, the human infant contains about 12 percent body fat. During the first years of life, body fat rises rapidly to reach a peak of about 25 percent by six months of age and then declines to 18 percent over the next ten years. At puberty, there is a significant increase in the percentage of body fat in females and a decrease in males. By age eighteen, males have approximately 15 to 18 percent body fat, and females have 25 to 28 percent. Be-

**TABLE 1**

<b>Classification of overweight and obesity by BMI, waist circumference, and associated disease risk</b>				
	<b>BMI <math>\text{kg/m}^2</math></b>	<b>Obesity class</b>	<b>Disease risk* relative to normal weight and waist circumference</b>	
			<b>Men = 102 cm (= 40 in) Women = 88 cm (= 35 in)</b>	<b>&gt;102 cm (&gt;40 in) &gt;88 cm (&gt;35 in)</b>
<b>Underweight</b>	18.5		—	—
<b>Normal +</b>	18.5–24.9		—	—
<b>Overweight</b>	25.0–29.9		Increased	High
<b>Obesity</b>	30.0–34.9	I	High	Very High
	35.0–39.9	II	Very High	Very High
<b>Extreme Obesity</b>	= 40	III	Extremely High	Extremely High

\*Disease risk for type 2 diabetes, hypertension, and CVD.  
+Increased waist circumference can also be a marker for increased risk even in persons of normal weight.  
*Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults—The Evidence Report. National Institutes of Health. Obes Res 1998;6 Suppl 2:51S–209S.*

Due to his enormous size, Frank Williams, age 16, weight 442 pounds, was placed on display at the St. Louis Exposition in 1893. Obese teenagers are now a much more common sight. Photo by McKnight, Paducah, Kentucky, circa 1893. ROUGHWOOD COLLECTION.

tween ages twenty and fifty, the fat content of males approximately doubles and that of females increases by about 50 percent. Total body weight, however, rises by only 10 to 15 percent: fat now accounts for a larger part of the body weight and lean body mass decreases.

### Risks Related to Obesity

As the BMI increases, there is a curvilinear rise in excess mortality. This excess mortality rises more rapidly when the BMI is above 30 kg/m<sup>2</sup>. A BMI over 40 kg/m<sup>2</sup> is associated with a further increase in overall risk and for the risk of sudden death. The principal causes of the excess mortality associated with overweight include hypertension, stroke, and other cardiovascular diseases, diabetes

mellitus, certain cancers, reproductive disorders, gall-bladder disease, and sudden death.

The insulin-resistant state or metabolic syndrome is strongly associated with visceral fat. It may include consequences such as glucose intolerance or type 2 diabetes mellitus, hypertension, polycystic ovarian syndrome, dyslipidemia (the state of abnormal—either higher or lower—values for blood fats), and other disorders. These are often responsive to weight loss, especially when this is achieved early and the loss is maintained.

### Development of Obesity

Several mechanisms lead to obesity, including neuroendocrine imbalances, particular drugs, diet, reduced energy expenditure, and genetic factors that lead to certain syndromes and predisposition to obesity. Obesity can follow damage to the hypothalamus in the brain, but this is rare. Cushing's disease is somewhat more common and can result in obesity. Treatment should be directed at the cause of the increased formation of adrenal corticosteroids.

Treatment of diabetics with insulin, sulfonylureas, or thiazolidinediones (but not metformin) can increase hunger and food intake, resulting in weight gain. Treatment with some antidepressants, anti-epileptics, and neuroleptics can also increase body weight, as can cyproheptadine (a serotonin antagonist that produces weight gain), probably through effects on the monoamines (including norepinephrine, epinephrine, dopamine, histamine, and serotonin) in the central nervous system.

Eating a high-fat diet and excessive consumption of sugar-sweetened beverages and the prevalence of abundant varieties of food in cafeterias or supermarkets are dietary factors in the development of obesity. Reduced energy expenditure relative to energy intake is another major component. Energy expenditure can be divided into four parts.

An inactive individual at rest burns between 800 and 900 kilocalories during a twenty-four hour period. This rate is lower in females than in males, and declines with age, and could account for much of the increase in fat stores if food intake does not decline similarly. The effect of physical exercise on metabolism is variable but on average is responsible for about one-third of the daily energy expenditure. From a therapeutic point of view this component of energy expenditure is most easily manipulated. Dietary thermogenesis is the energy expenditure that follows the ingestion of a meal. Heat produced by eating may dissipate up to 10 percent of the ingested calories. These thermic effects of food are one type of metabolic "inefficiency" in the body, that is, where dietary calories are not available for "useful" work. In the obese, the thermic effects of food are reduced particularly in individuals with impaired glucose tolerance or diabetes. Acute over- or underfeeding will produce corresponding

shifts in overall metabolism, which can be as large as 15 to 20 percent.

Genetic factors can produce some types of obesity that are easily recognized. Among these types of obesity are: (1) the Bardet-Biel syndrome, characterized by retinal degeneration, mental retardation, obesity, polydactyly, and hypogonadism; (2) the Alstrom syndrome, characterized by pigmentary retinopathy, nerve deafness, obesity, and diabetes mellitus; (3) Carpenter syndrome, characterized by acrocephaly (abnormalities in the facial and head bones), mental retardation, hypogonadism, obesity, and preaxial syndactyly (extra fingers or toes on one hand or foot); (4) the Cohen syndrome, characterized by mental retardation, obesity, hypotonia (reduced tone of the muscles, resulting in a “floppy” muscle mass), and characteristic facies (an appearance of the face that is typical of specific genetic diseases); (5) the Prader-Willi syndrome, characterized by hypotonia, mental retardation, hypogonadism, and obesity; and (6) the pro-opiomelanocortin (POMC) syndrome, characterized by defective production of POMC that is recognized as a red-headed fat child with a low plasma cortisol (a value that is below the normal range).

If both parents are obese, about 80 percent of their offspring will be obese. If only one parent is obese, the likelihood of obesity in the offspring falls to less than 10 percent. Studies with identical twins suggest that inheritance accounts for about 70 percent and environmental factors (diet, physical inactivity, or both) account for 30 percent of the variation in body weight. Deficiency of the gene leptin and deficiency of the leptin receptor are rare, but are associated with massive human obesity. Absence of convertase I has also been associated with obesity in one family. The most common defects associated with massive obesity are abnormalities in the melanocortin receptor system—up to 4 percent of massively obese people may have this type of defect.

### Evaluation of the Obese Patient

A medical evaluation should include the expected medical history, family history, personal and social history, and review of the systems of the body with a particular focus on the medications that can cause weight gain. A physical examination should include an assessment of the patient’s height, weight, waist circumference, blood pressure, and level of health risk due to obesity. Laboratory tests should include a lipid panel, glucose level, chemistry panel for hepatic (liver) function and uric acid, thyroid function testing, and, if indicated a cortisol level.

### Evaluating Risk Using the Body Mass Index (BMI)

Individuals with a normal BMI (20–25 kg/m<sup>2</sup>) have little or no risk from obesity. Any individual in this weight range who wishes to lose weight for cosmetic reasons should do so only with conservative methods. Individuals with a BMI of greater than 25 to 29.9 kg/m<sup>2</sup> are in the low-risk group for developing heart disease, hyper-

tension, gallbladder disease, and diabetes mellitus associated with obesity. They too should be encouraged to use low-risk treatments, such as caloric restriction and exercise. Individuals with a BMI of 27 to 30 kg/m<sup>2</sup> or more who have diseases related to obesity may use adjunctive pharmacotherapy for weight loss.

Individuals with a BMI of 30 to 40 kg/m<sup>2</sup>, have moderate risk for developing diseases associated with obesity. Diet, drugs, and exercise would all appear to be appropriate forms of treatment. Individuals with significant degrees of excess weight often find exercise difficult. However, exercise is very important in helping to maintain weight loss. The use of weight loss medications, as an adjunct to treatment, may also be useful in this group. Individuals who have a BMI above 40 kg/m<sup>2</sup> have a high risk of developing diseases associated with their obesity. Moderate to severe restriction of calories is the first line of treatment, but for some of these patients surgery may be advisable.

### Treatment of Obesity

Any diet must reduce an individual’s caloric intake below daily caloric expenditure if it is to be successful. This requires an assessment of caloric requirements, by estimating caloric expenditure from desirable weight tables; for men, multiply desirable weight by 30 to 35 kilocalories/kilogram, (14–16 kilocalories/lb.); for women, multiply desirable weight by 25 to 30 kilocalories/kilogram (12–14 kilocalories/lb.). After assessing caloric requirements, a reasonable calorie deficit can be prescribed. A caloric deficit of 500 kilocalories/day (3,500 kilocalories/week) will produce the loss of approximately one lb. (0.45 kilograms) of fat tissue each week. Table 2 gives a list of diets divided into different levels of energy.

The very low calorie diet (below 800 kilocalories) was developed to facilitate the rate of weight loss since lower energy intake should lead to greater energy deficit. In free living people, however, diets with 400 kilocalories/day have not produced greater weight loss than those with 800 kilocalories/day, suggesting either that they are harder to adhere to or that there is an adaptation in energy expenditure. In either case, these diets should only be used under appropriate medical supervision.

TABLE 2

#### Characterization of diets by composition

Type of diet	Calories	Fat g (%)	Carbohydrate g (%)	Protein g (%)
Typical American	2,200	85 (35)	274 (50)	82 (15)
High-fat, low carbohydrate	1,400	94 (60)	35 (10)	105 (30)
Moderate-fat	1,450	40 (25)	218 (60)	54 (15)
Low & very low fat	1,450	16–24 (10–15)	235–271 (65–75)	54–72 (15–20)

Obesity is a highly charged subject that has assumed broad sociological implications. In this 1998 photographic study called "Servitude I" by American artist Lynn Bianchi, several issues are exposed through novel inversions of female roles: body image, incessant snacking, and anorexia, to name three. Here it is the overly thin female who acts the role of caryatid-slave to an Earth Mother figure who never stops eating. PHOTO COURTESY OF THE ARTIST AND THE RALLS COLLECTION, INC., WASHINGTON, D.C.

**Types of diets.** There are several types of diets with more than 800 kilocalories/day that usually have more than 1,200 kilocalories/day. They can be divided into several categories. These categories are based on the relative proportion of macronutrients included in the diet and whether they use special foods. For all diets it must be true that they reduce the calorie intake to produce a negative energy balance. Low-carbohydrate diets are touted because they produce ketosis (a state of increased ketones associated with diabetes and fasting) and allow you to eat all of the protein and fat you want. This ends up reducing total calorie intake to about 1,500 kilocalories/day. Since these diets generally have carbohydrate levels below 50 g./day they are ketogenic and can be monitored clinically by the appearance of ketones in the urine. They vary in the level of fiber that is employed. The Atkins diet has low fiber levels, the Sugar Busters diet higher fiber levels.

Low-fat diets recommend fat intake in the range of 10 to 20 percent of calories. The higher carbohydrate in-

creases fiber intake. These diets were developed in a setting designed to reverse the atherosclerotic plaques associated with risks for heart disease, but because of the high fiber content they were often associated with weight loss. Moderate fat levels with higher carbohydrates are characteristic of many widely recommended "healthy diets." For weight loss, the New York Health Department recommends the Prudent Diet, which has stood the test of time.

The portion-controlled diet makes use of prepared foods that have a narrow range of calories. This includes liquid or powdered drinks as well as frozen or canned entrees that have about 300 kilocalories/meal. These can be combined conveniently and thus removes the problem of counting calories from the individual. A number of popular diets focus on a single food, and although nutritionally unbalanced, they are simple to follow and the monotony of single items tends to limit food intake.

**Food Guide Pyramid.** The Food Guide Pyramid provides an approach to evaluating the quality of your diet. At the bottom of the pyramid are the grains, beans, and starchy vegetables that provide vitamins, minerals, fiber, and energy; six or more servings are recommended. On the next level are the vegetables (3–5 servings) and the fruits (3–4 servings). On the third level are the meats, fish, poultry, and nuts (2–3 servings) along with the milk and yogurt (2–3 servings). At the top are the fats, sweets, and alcohol. Reducing the number of servings proportionally will provide you with a calorie-reduced diet. Most important for the dieter, however, is to sharply reduce the fats and sugar at the top of the pyramid and to reduce or eliminate alcoholic beverages. Not only do alcoholic beverages have calories, their consumption tends to reduce the individual's control in selecting the quality and quantity of foods to eat.

**Changing behavioral patterns of eating.** The basic principles of behavioral approaches for obesity can be summarized under the ABCs of eating.

- The A stands for antecedent. If one looks at eating as the response to events in the environment, then the antecedent events are those that trigger eating.
- The B stands for the behavior of eating. This includes among other things the place, the rate, and the frequency with which an individual eats. If the act of eating can be focused at one place with one plate and place setting it can help to provide control over eating.
- The C is the consequence of the eating. The feelings an individual has about eating can be altered, and rewards for changing eating patterns can be instituted.

**Exercise and physical activity.** The only part of energy expenditure that is amenable to significant manipulation is physical activity. During sleep, the lowest level of ac-

tivity, approximately 0.8 kilocalories/minute is consumed. Thus, if an individual sleeps for an entire 24 hours, approximately 1,150 calories will be expended. Reclining increases this level to approximately 1.0–1.4 kilocalories/minute. Obese and diabetic patients should be encouraged to increase their physical activity for two reasons: First, it consumes calories, but second, and more important, exercise increases glucose utilization and may improve insulin sensitivity.

**Drug treatment of obesity.** Only a few drugs have been approved by the Food and Drug Administration for treatment of obesity. Studies following individuals who have used these drugs for two years have been published for sibutramine (Meridia) and orlistat (Xenical). Weight-loss drugs should be reserved for patients with moderate- or high-risk obesity (BMI > 30 kg/m<sup>2</sup>) or a BMI above 27 if they have other significant diseases related to obesity. They should be considered for the patient who has failed to lose weight with other methods. Herbal products containing ephedra and an herbal source of caffeine can also produce weight loss when used in accordance with the package instructions.

**Surgery.** Gastric operations reduce the size of or bypass the stomach, but should be reserved for people with a BMI above 40 or when recommended by a physician.

### The Obese Child

Estimates of the prevalence of obesity in children range from 3 to 15 percent. This figure has been rising more rapidly than in the rest of the population. The appearance of obesity in childhood and particularly adolescence is important because it most often persists into adult life. It may be a precursor to the appearance of type 2 diabetes in adolescents. The possibility of treatment should be considered for children who are above the seventy-fifth percentile of weight for height, and might be encouraged for those who are above the ninety-fifth percentile of weight for height. The treatment of prepubertal children should probably involve both parents and child since at this age the principal control of food availability is in the hands of the parents. For adolescents, however, it may be better to separate patient and parents, since the interaction between these groups may be part of the problem. Where growth has not reached its fullest extent, dietary restriction should attempt to reduce further weight gain. Severe caloric restriction and the use of appetite-suppressing drugs may slow height growth. For both children and adolescents, involvement in a regular exercise program is probably the first line of treatment.

**OIL.** Oil is liquid fat, usually plant-derived, used as a cooking medium, as a lubricant to keep food from sticking to pans, and as a source of flavor. Oil from animal sources, particularly fish oil, is also used as a nutritional supplement. Oil is also ubiquitous in processed foods.

The difference between oil and fat is that oil is liquid at room temperature while fat is solid. Chemically, both are composed of hydrocarbon chains and are potent sources of energy. The strong molecular bonds of fats and oils make them relatively resistant to heat and thus suitable for high-heat cooking methods such as deep-frying. Oil can be used in conjunction with other fats, such as butter, to raise the temperature of the other fat at which it would otherwise begin to break down and smoke.

### History of Oil

Olive oil and sesame oils are among the most ancient oils in the Western world, dating back to 4,000 years or more. Olive trees are relatively simple to cultivate and, once the olives are prepared, the oil can be obtained by pressing. Both olive oil and sesame oil were used in southern Europe, while northern countries typically used animal fats such as lard or goose fat.

In the Orient, oil was pressed from soybeans, while sesame, mustard seed, and safflower oils were used in India and ancient Egypt. Peanuts, corn, and sunflower seeds were available in the New World, but oil was generally extracted only from squash seeds, especially squash belonging to the species *Cucurbita pepo*.

The nineteenth century saw the rise of international trade in tropical oils, particularly palm and coconut oil. The raw materials, which included hearts of palm and dried coconut meat (copra), were exported from Africa and the Pacific islands to industrial countries to be pressed for oil. The vast production of corn in the United States provided a source of oil to be used in cooking and in the manufacture of oleomargarine.

Olive oil is one of the major culinary oils employed in the Mediterranean region. This home-pressed oil is being bottled for private use at Dolcedo, Italy. © OWEN FRANKEN/CORBIS.

In nineteenth-century Africa, both the French and British introduced larger-scale peanut farming specifically for peanut oil, which was used as an adulterant in cheap grades of olive oil, and as a base ingredient in soap.

### Composition of Oils

Oils, like other fats, consist mostly of triglycerides, which are three fatty acids attached to a molecule of glycerol (an alcohol built around three atoms of carbon). A fatty acid consists of a carboxyl group (carbon, oxygen, and hydrogen linked together), which in turn is linked to a hydrocarbon chain. The more the hydrocarbon chain is filled with hydrogen atoms, the more chemically stable it will be. A fatty acid fully loaded with hydrogen is said to be “saturated,” while a less hydrogen-rich acid is “monounsaturated” or “polyunsaturated,” depending on its structure. Oleic acid is a common monounsaturated fat, while linoleic acid is the most common polyunsaturated fatty acid.

The more saturated a fat is, the more likely it is to be solid at room temperature (such as lard or shortening). Oils are liquid because they are less saturated than fats. They are also less shelf-stable because their chemical structures are more likely to be affected by exposure to oxygen, causing them to become rancid or develop off-flavors. To make the product more stable, food processors pump hydrogen through the oil to fill in the gaps in its chemical structure, a process known as “hydrogenation.” Highly hydrogenated oil is creamy or solid at room temperature, useful for making oleomargarine or other processed food products.

Oils generally have about the same caloric value of approximately 120 calories per tablespoon whether the fatty acids are saturated or not. More important to health-conscious consumers is the role of fatty acids in raising or lowering the presence in the bloodstream of the high-density lipoprotein (HDL) or low-density lipoprotein

(LDL) associated with cholesterol. HDL (the “good cholesterol”) is a beneficial substance that helps the body get rid of excess cholesterol, while LDL (the “bad cholesterol”) builds up in the arteries and can increase the risk of heart disease. Eating foods high in monounsaturated fatty acids is believed to help lower LDL cholesterol levels and decrease the risk of heart disease, while the consumption of saturated fats may increase levels of LDL and total cholesterol. The consumption of polyunsaturated fats in place of saturated fats decreases LDL cholesterol levels. The American Heart Association recommends the consumption of oils that have no more than two grams of saturated fat per tablespoon.

Unsaturated fat content is a major selling point for household oils. One of the major oils on the market, canola oil, was developed specifically to appeal to consumers concerned about fat content. Canola—short for “Canadian oil”—is a variety of the rapeseed plant developed in Canada with less fatty acid than the traditional variety and thus a lower level of saturated fat than most other oils.

The chemical structure of oils makes them relatively stable at high temperatures, but at some point oil begins to break down and give off smoke; beyond this point there is danger of fire. The smoke point for most oils is around 410°F (210°C), although some oils have even higher smoke points. The smoke point gets lower as oil is re-used due to degradation of chemical bonds and contamination of the oil with food particles. Commercial operations that re-use oil will pass it through a filter to take out the contaminants.

### Sources of Oil

In addition to olives, oil is obtained from legumes such as peanuts and soybeans; from the seeds of many plants, including corn, rapeseed (canola), sesame, cottonseed, sunflower, palm, safflower, coconut, grapeseed, mustard, pumpkin, and avocado; and from tree nuts such as wal-

TABLE 1

#### Smoke Points of Common Oils

Oil	Smoke point (degrees F)
Sunflower	392
Olive	410
Corn	410
Peanut	410
Soybean	410
Cottonseed	435
Avocado	435
Canola	437
Grapeseed	446

nuts, almonds, hazelnuts, and pistachios. Tree nut oils are usually expensive and do not respond well to high heat, so they are used primarily to dress salads or to add flavor to baked goods.

The finest oils are simply extracted from the raw material (such as olives or nuts) by pressure. This is called “cold pressed” or “first pressed” oil. Oil that remains bound up in the raw material can be extracted by heat or chemical solvents.

Oils labeled by specific names, such as peanut oil, are obtained from those particular plants; a product labeled merely “vegetable oil” is a blend of various oils. In the production of vegetable oils, seeds are cracked, cooked, and run through a press to extract readily obtainable oil. The pulp is further processed to obtain the rest of the oil, which is neutral and tasteless; if flavor is desired, the oil can be mixed with the product of the first pressing to restore flavor and color.

### Uses of Oil

Oil has a variety of uses in cooking, most of them based on its ability to transfer heat to the food while remaining stable itself. Asian food is often stir-fried in a little

hot oil, just enough to keep the food from sticking to the pan. Chicken can be sautéed or fricasseed in a few tablespoons of oil, while pieces of breaded fish can be fried in shallow oil—perhaps a quarter of an inch deep.

Frying large pieces of food in deep oil requires a temperature of 350° to 375°F (177° to 191°C). At that temperature, the hot oil will sear the surface of the food being fried, trapping moisture within the food. The food thus cooks in its own moisture rather than in the oil, which is why properly fried food is not greasy. Greasiness results from frying at a temperature lower than optimal.

In Italy, olive oil is used as a dipping sauce for bread at the table. Olive oil is preferred as a salad dressing because it has its own flavor to contribute to the dish.

In food manufacturing, oils are used in a host of products, ranging from soups and gravies, salad dressings, bread and rolls, and fried foods to nondairy toppings and frozen desserts, coffee creamers and cocoa mixes, candy bars and cakes, and in most processed snack foods.

### Fish Oil

Some species of fish such as Atlantic menhaden have high levels of certain essential fatty acids, called omega-3 fatty

acids, which the human body is not able to synthesize by itself and must obtain from food. Oil made from these fish is sold as a nutritional supplement. Menhaden oil is used in the production of margarine and shortening in Europe and has been approved for use in the United States.

**ONIONS AND OTHER ALLIUM PLANTS.** *Allium* crops have been cultivated for millennia by people worldwide for sustenance, flavor, and medicinal purposes. Each of these three properties is closely connected to a suite of unique organosulfur compounds present in *Allium* crops that make them distinct from other wild and cultivated food plants. These compounds impart the characteristic flavors and odors of edible alliums. A substantial body of scientific literature suggests that these organosulfur compounds likely arose through natural selection for pest resistance. In a fortuitous circumstance, humans find these odors and flavors appealing, thus what confers functional significance to the *Allium* crop for its survival also confers culinary significance to the *Allium* consumer for gastronomic pleasure.

Seven major allium crop complexes are recognized, five of which contain a single allium crop (Table 1). These five are bunching onion (*fistulosum*), chives (*schoenoprasum*), Chinese chives (*tuberosum*), garlic (*sativum*), and rakkyo (*chinense*). The remaining two complexes contain four separate crops (leek, kurrat, great-headed garlic, and pearl onion) in the case of *ampeloprasum* and two different crops (onion and shallot) in the case of *cepa*. Each of these crops represents a unique modification of the leaf. In the allium crops where bulbs are prominent, leaf bases are swollen due to the accumulation of carbohydrates from photosynthesis. In those crops where pseudostems are the edible portion, overlapping leaf bases form a hollow column that has the appearance of a stem, such as the base of the leek. For other allium crops the edible portion is the leaf blade, which also serves as the primary photosynthetic organ. These seven crop complexes are grown and consumed worldwide for a multiplicity of uses.

TABLE 1

#### The seven primary edible allium crop complexes

Species Complex	Crop	Variety	Storage Organs
<i>cepa</i>	bulb onion shallot	<i>cepa</i> <i>ascolonicum</i>	foliage leaf bases and bladeless leaf sheaths
<i>fistulosum</i>	bunching onion	NA	foliage leaf bases, bulbs absent
<i>schoenoprasum</i>	chives	NA	foliage leaf bases, bulbs absent
<i>tuberosum</i>	Chinese chives	NA	rhizomes, bulbs absent
<i>ampeloprasum</i>	leek kurrat great-headed garlic pearl onion	<i>porrum</i> <i>kurrat</i> <i>holmense</i> <i>sectivum</i>	bulbs generally absent, cloves like garlic in great-headed garlic and pearl onion; pseudostem in leek and kurrat
<i>sativum</i>	garlic	<i>sativum</i>	swollen, bladeless sheaths (cloves)
<i>chinense</i>	rakkyo	NA	swollen, foliage leaf bases, bulbs prominent

NA = not applicable

#### Taxonomic History

The genus *Allium* contains more than five hundred species, including many ornamental and edible plants. The genus has been assigned to the family Alliaceae, although for many years it was classified with both the Amarylidaceae and the Liliaceae. Edible alliums are important staples in the diets of many of the world's cultures. Most of the edible alliums are native to the mountains of central Asia, and a number of alliums are still collected from the wild in this region. Distribution of *Allium* crops ranges widely throughout the Northern Hemisphere and in mountainous regions of the tropics. The area of greatest diversity is the mountains of central Asia, including Afghanistan, Tajikistan, Pakistan, and parts of Siberia and China.

Many edible alliums are classified into two subgenera, *Rhizirideum* and *Allium*. In subgenus *Rhizirideum* the sections *Cepa*, *Schoenoprasum*, and *Rhizirideum* are comprised of the species *cepa*, *fistulosum*, *schoenoprasum*, and *tuberosum*. In the subgenus *Allium* the section *Allium* is comprised of the species *ampeloprasum*, *sativum*, and *chinense* (Hanelt, 1990; Brewster, 1994). Together these seven species contain the primary edible alliums consumed throughout the world. G. R. Fenwick and A. B. Hanley (1985) also describe a number of other minor alliums consumed as vegetables or herbs, including the topset onion, the tree onion, the Wakegi onion, and others. These minor alliums are primarily from the *Allium cepa* group and are discussed in some detail in Henry A. Jones and Louis K. Mann's *Onions and Their Allies* (1963).

The topset onion, tree onion, and Egyptian topset onion (*A. cepa* subvarieties *viviparum*, *bulbiferum*, and *proliferum* respectively) form bulbils in their inflorescences. Bulbils are small, bulblike structures used as vegetative propagules for these alliums.

## Crop Histories

**Onion and shallot.** The wild progenitor of onion is not known, although P. Hanelt (1990) and M. J. Havey (1995) have suggested it may be *Allium vavilovii*. Bulb onion was domesticated from a plant that likely had a long juvenile phase and grew as a perennial. Selection pressure during domestication was for larger bulbs that grew more rapidly, a biennial life cycle that concentrated vegetative growth into one season, and barriers to crossing with other wild species (Brewster, 1994). The cultivated *Allium cepa* has been placed into two horticultural groups by Hanelt (1990), the Common Onion group and the Aggregatum group. The Common Onion group includes the typical bulb onion, while the Aggregatum group consists of those subspecies or varieties of *A. cepa* whose lateral buds have been active, thereby forming clusters of smaller bulbs. These types of *A. cepa* have been further subdivided into multiplier or potato onions and shallots. Multiplier onions may possess as many as twenty small bulbs that are short and wide, whereas shallots form clusters of smaller, narrow separate bulbs (Jones and Mann, 1963). Most of the plants in the Aggregatum group are vegetatively propagated for horticultural use. Aggregatum group crops are found at extreme northern latitudes, such as Finland and Russia, and also in the tropics, but for different reasons. The short life cycle of Aggregatum group crops favors the short growing season in northern latitudes, whereas the intense pest pressure of tropical environments favors a short-season crop that can be grown from a vegetative propagule rather than from seed (Brewster, 1994).

Onion plants form bulbs in response to specific day lengths and temperatures. This photoperiodic response includes two primary categories, long day and short day. The long-day onion plant requires a day length of at least fourteen hours (actually a night length of less than ten hours) to initiate bulb formation, while short day onion plants require between twelve and fourteen hours of day length to form bulbs. Long-day onions are grown in the northern latitudes, often from seed or transplants sown in early spring. Bulb formation takes place during the summer months, and bulb harvest is during the later summer and the fall. The short-day onion is grown in warmer climates, where it may be sown in the fall and overwintered in the field. Bulb formation is in the spring, and harvest is in early summer.

Long-day onions were cultivated in Europe for many centuries and adapted to northern latitudes. Like many root vegetables developed for consumption during winter months in cold climates, these long-day onions were harvested in late summer and fall and stored at cold tem-

peratures. For this reason these cultivars or landraces became known as storage onions. Populations of storage onions developed in England and other parts of northern Europe and in the early seventeenth century were taken to the New World, where they were planted in the area around Salem, Massachusetts (Goldman et al., 2000). Selection for proper bulb formation and storability led to the development of popular cultivars, such as the Danvers Yellow Globe, which became a progenitor population for virtually all long-day storage onions in the United States during the nineteenth and twentieth centuries.

Short-day onions were cultivated in the Middle East and in many southern European countries for centuries, and immigrants from Italy and Spain brought these cultivars and landraces to the United States in the late nineteenth century (Goldman et al., 2000). The first southern European onions in the United States were likely the

Giant-sized onions became popular toward the end of the nineteenth century, due in part to the fame of the Giant Zittau onion of Germany. Burpee's Giant Gibraltar onion was an attempt to breed an American counterpart to that highly successful variety. Chromolithographic advertisement from a Burpee seed catalog. © CYNTHIA HART DESIGNER/CORBIS.

Topsetting onions are also called Egyptian onions, tree onions, and Catawissa onions. Contrary to popular belief, they are not from Egypt, and began to appear in English and American kitchen gardens only in the 1790s. They were highly valued for their early spring greens and for the bulbils shown here, which were used like pearl onions in pickles. Zammit-Havermann Garden, Toronto, Canada. PHOTO ROB CARDILLO.

Bermuda types, which originated in Italy and were first grown in the United States in southern Texas. The second type of onion introduced from southern Europe was the Babosa onion from Valencia, Spain, which was likely introduced early in the twentieth century. Fabian Garcia's early breeding work at the New Mexico Agricultural Experiment Station developed the Early Grano onion, an important progenitor of many of the sweet, mild onions grown in the southern United States (Brewster, 1994; Goldman et al., 2000). These onions were further selected into a number of important populations, including the Texas Early Grano and Granex series, which are important short-day onions in the U.S. market.

**Garlic.** Garlic almost certainly originated in the mountains of central Asia. Although its exact progenitor is unknown, it may be *A. longicuspis*. For thousands of years garlic has been propagated by asexual means because fer-

tile flowers were extremely rare. At the end of the twentieth century several reports of fertile garlic clones, both in the wild and in cultivation, initiated intense interest in seed propagation of garlic, which appears to be a realistic proposition (Pooler and Simon, 1994). Seed production is important for several reasons, including the possibility of reducing the spread of viral diseases by going through a reproductive phase and the potential for breeding garlic for improved characteristics. Despite the fact that little to no sexual reproduction of garlic has taken place under cultivation, much phenotypic variation exists among cultivars, likely due to the selection of interesting and favorable mutants.

**Leek, kurrat, great-headed garlic, and pearl onion.** The *ampeloprasum* group includes four primary crops, all of which can be freely crossed and interbred. Wild *A. ampeloprasum* is found in a broad geographic range that includes western Iran through the Mediterranean to Portugal (Brewster, 1994).

The leek group is characterized by the development of a pseudostem, which is actually the edible part of the leek plant. The pseudostem is so called because the concentric overlapping leaf bases fold over each other to create a hollow stemlike structure, although botanically the edible portion of the leek is not a stem. Leeks are well adapted to cool climates and are grown throughout northern Europe. Unlike bulb onions, leeks do not have specific photoperiodic requirements for pseudostem formation and can thus be grown in a wide range of latitudes.

The kurrat group includes those *A. ampeloprasum* selected for edible leaves and short pseudostems. The crop is popular in Egypt, where the leaves are repeatedly cut and harvested every three to four weeks over an eighteen-month period (Brewster, 1994).

The great-headed garlic group includes plants that form large cloves similar to garlic cloves, however the inflorescence is large and leeklike. Called elephant garlic by many commercial growers, it typically is much larger than a garlic plant and can produce up to six large cloves at the base of the flower stalk. When the plant does not flower, only a single large clove, known as a "round," is produced.

Pearl onion is a minor *Allium* crop grown in certain parts of Europe. The plant forms a cluster of small, spherical, white-skinned bulbs. In the United States, products marketed as pearl onion may in fact be small bulbs of *A. cepa* rather than the true pearl onion. Among U.S. horticulturists, the true pearl onion is often called Portuguese leek.

**Bunching onion.** The bunching onion has been the primary *Allium* crop in many parts of Asia for millennia and is still a major component in the diet in China and Japan. Bunching onions appear similar to bulb onions during early growth stages, but bunching onions do not form bulbs and instead are harvested for their green foliage.

*Allium fistulosum* may derive from the wild *Allium altaicum*, which grows in the mountains of southern Siberia and Mongolia and is interfertile with *A. fistulosum*.

In the U.S. market the consumer is usually presented with green onions or scallions that are likely the bulb onion *A. cepa* harvested for its green foliage. It is also possible that these green onions were produced from an interspecific hybrid between *A. cepa* and *A. fistulosum* known as “Beltsville Bunching” that has been a mainstay of bunching onion production in the United States for more than fifty years. Thus the green onions or bunching onions in the U.S. market may be of several different genetic backgrounds.

Bunching onion cultivars have been developed for a variety of market classes. These classes are primarily separated by the geographic areas in which the plants can be grown and by the quality of the foliage. Certain consumers prefer blanched pseudostems instead of green pseudostems. Cultivation of the former is accomplished by mounding soil on the developing plants, thereby reducing the amount of chlorophyll and producing a more tender, lighter-colored pseudostem.

**Rakkyo.** This allium crop is grown mainly in Japan and China, where it produces small bulbs that are mostly consumed pickled. The plants resemble chives but develop elongated bulbs in the summer.

**Chives.** Chives, which grows wild in Eurasia and in America, is the most widely distributed allium species. It is extremely cold hardy and is winter dormant, and it can grow in latitudes as high as 70° (Brewster, 1994). Chives form a cluster of low-growing, narrow, hollow leaves. After every two or three leaves have formed, axillary buds form side shoots that then allow for the development of a cluster of shoots (Brewster, 1994). The shoots are attached to each other on a rhizome.

**Chinese chives.** *Allium tuberosum* grows wild in East Asia and is cultivated for its garlic-flavored leaves and immature flowers. It forms rhizomes similar to those of chives, and the leaves arise as dense clumps from these rhizomes (Brewster, 1994). Unlike true chives, which has a hollow stem, the leaves of Chinese chives are flat.

### Chemical Constituents and Culinary Significance

The word “allium” derived from the Greek phrase “to leap out,” thereby suggesting a strong interaction between the crop and its consumer. Worldwide the edible alliums are prized for their unique flavors. These flavors are derived from a suite of unique organosulfur compounds that likely have their origin as a defense strategy, protecting allium plants from pests. Although they possess some toxicity for insect and microbial pests, their levels of toxicity for humans and larger animals is far less and in most cases nonexistent. Several exceptions exist, however, and these are discussed under the pharmacological properties of allium crops below.

Like all plants, alliums uptake the necessary element sulfur as sulfate from the soil. Sulfate is then used to form the amino acids cysteine and glutathione, which in turn form the gamma glutamyl peptides. These peptides serve as building blocks for the allium flavor precursors, known collectively as the alk(en)yl-L-cysteine sulfoxides or ACSOs. The ACSOs are present in the mesophyll storage cells, inside the cell’s cytoplasm. Each allium crop is characterized by a different number and ratio of these ACSOs, which ultimately determine its flavor. For example, onion contains three ACSOs, while garlic contains four. The balance of these ACSOs in onion and garlic are different, resulting in flavor differences between the vegetables. Knowing the ACSO profile can help predict the flavor of an allium, because they are directly responsible for the flavor components as described below.

The ACSOs are considered flavor precursors because they do not impart flavors directly. Rather, it is only upon tissue disruption that allium crops yield their unique flavors and odors. This is accomplished through a chemical reaction that begins when the enzyme alliinase, stored in the bundle sheath cells and protected from the ACSOs by a membrane, comes into contact with the ACSOs after tissues are cut. Thus the scent of an unchopped onion bulb is completely different from the scent after tissues have been chopped, because the enzymatic lysis of the ACSOs initiates the development of the thiosulfonates, which are actually responsible for allium flavors.

As soon as allium tissues are disrupted, such as by a kitchen knife, the transient sulfenic acids are formed as well as the by-product pyruvic acid. Pyruvic acid has been used extensively as an indirect measure of onion pungency because the amount of enzymatically formed pyruvate is positively correlated significantly with a taste perception of pungency (Wall and Corgan, 1992). In all alliums except onions the sulfenic acids are rapidly converted into thiosulfonates, which are the compounds responsible for the flavors of allium vegetables. This conversion also takes place in onions, however, immediately prior to thiosulfonate formation, the compound propanethiol sulfoxide is formed. Propanethiol sulfoxide, also known as the lachrymatory factor, is responsible for the formation of tears in the eyes of those close enough to the chopped onion to intercept the airborne compound. Presumably the formation of tears is caused by the interaction of this sulfur compound with the eye’s nerve cell membrane, causing the formation of sulfuric acid.

Thiosulfonate accumulation in crushed or cut allium tissues is perceived by the nose, the eyes, the tongue, and the skin. Because allium crops contain different ACSOs, they also contain different kinds and amounts of thiosulfonates, which in turn leads to different flavors. Thiosulfonate formation at room temperature is complete after thirty minutes (Thomas and Parkin, 1994). Chopped allium tissues therefore have differential thiosulfonate

profiles depending upon the length of time they have been allowed to sit and the temperature at which they have been prepared.

Typically most consumers process cut alliums by boiling or by frying or sautéing in oil. These two processes yield different by-products. Boiling chopped garlic results in the formation of various sulfides, including diallyl disulfide and diallyl trisulfide. Sautéing in oil produces the vinyl dithiins and ajoene (Lawson, 1998). The transformation of sulfur compounds into thiosulfonates and downstream reactions that transform the thiosulfonates into sulfides and dithiins is an area of great interest and investigation in the allium research community.

### Biology of Vegetable Alliums

Most of the edible alliums possess some variation of the leaf that creates their vegetable form. Those that form bulbs do so because the base of the leaf begins to swell with carbohydrates from photosynthesis. The concentric swollen leaf bases make up the structure of the onion bulb. Similarly the swollen leaf base and its protective leaf sheath make up the clove that is a part of the garlic bulb. Thus the bulb is nothing more than fleshy leaves or leaf bases on top of a short, flattened stem. Those alliums that form a pseudostem, such as leek, do so because the overlapping leaf bases form a hollow stemlike structure. These leaf bases do not swell but make up the edible portion of the crop just the same. And of course those vegetable alliums that are consumed for their leaf blades typically do not form swollen structures such as bulbs. In all cases a short, flattened stem is found under these leaf bases. It is likely that this stem has been shortened during the evolution of these allium crops, resulting in larger and more-prominent leaf bases and storage tissues.

These many variations on leaf morphology illustrate an important principle of crop domestication. Many of our most important crop plants occur in complexes where multiple morphological forms of a single species have been selected by humans to serve a variety of different needs. For example, the crop species in the *Brassica oleracea* complex, including cabbage, broccoli, cauliflower, kale, collards, and Brussels sprouts, all possess variations that partition their photosynthate into different storage organs. In the case of cabbage the photosynthate is stored in leaf tissue packed into a compact rosette. In the case of Brussels sprouts the axillary buds are activated, and smaller headlike structures become the item of commerce. In the case of broccoli photosynthates are partitioned into the thickened stem and immature inflorescence. Similar to allium crops, the variations in morphology serve the purpose of producing different crops for different uses. Among cultivated plants the alliums are unique in that their multiplicity of forms is based on how and where the photosynthate is partitioned in the leaf.

Another unique biological feature of the alliums is the presence of bulbils in the inflorescence. Bulbils are simply small bulblike structures that form in leaf axils, particularly in the inflorescence, of many allium crops. Bulbils are also comprised of leaf tissue but are not formed from swollen leaf bases as onion and garlic bulbs are. Rather, they represent a unique form of propagule from which alliums can be vegetatively propagated in a clonal fashion. The presence of bulbils in the inflorescence can also be a diagnostic character for differentiating alliums. They are common in garlic, are not present at all in Chinese chives and rakkyo, and occasionally are present in leek and kurrat.

### Pharmacological Properties

And if the boy have not a woman's gift to rain  
a shower of commanded tears,  
An onion will do for such a shift,  
which in a napkin being close conveyed,  
Shall in despite enforce a watery eye.

(William Shakespeare, *The Taming of the Shrew*, cited in Block, 1992)

Alliums may have been cultivated originally for their medicinal properties and only later developed into flavorants, although it is possible these two discoveries occurred simultaneously or in close proximity. Many of the most common vegetable crops, such as lettuce, tomato, and others, were originally used as medicinal plants prior to their widespread use as food (Rubatzky and Yamaguchi, 1997).

The Egyptians made extensive use of alliums to treat a variety of ailments, many of which are recorded in the Codex Ebers, a document at least 3,500 years old (Block, 1985). Documentation of their use in ayurvedic medicine in India, Western-style medicine in Greece, and Eastern-style medicine in China abounds (Lawson, 1998). Evidence also indicates that early Olympic athletes were fed alliums to promote blood circulation and to attain peak performance and that Europeans have used alliums to treat blood clots in horses and other domestic animals for many centuries (Block, 1985, 1992). Alliums were important in warding off plague and other microbial infections over the centuries (Lawson, 1998) and in treating dysentery, smallpox, and many other maladies during the twentieth century. Indeed edible alliums have been more widely used than many synthetic medicines for an incredibly diverse array of conditions.

The rising importance of synthetic, mono-molecular drugs during the twentieth century, particularly in the United States, resulted in a dearth of interest in naturally derived whole foods as medicines during that period. However, in the last decade of the century many people in the West became increasingly interested in the potential health functionality of food. In fact many consumers began to purchase food for these very properties (Sloan, 2000). The folkloric documentation of these

crops as curatives is highly informative with respect to the potential health functionality of alliums in the diet. Many properties mentioned in this way have been partially confirmed by modern medical investigation.

Historically allium crops have been used to treat a wide range of ailments, but the most prominent has been cardiovascular disease. Within the rubric of this disease, allium intake has been associated with significant reductions in blood pressure, cholesterol, and platelet aggregation (Block, 1992). Reductions in each of these parameters have been measured in clinically relevant feeding trials (Lawson, 1998), suggesting the potential for dietary intervention with edible alliums for cardiovascular disease. The antiplatelet, or antithrombotic, potential of onions appears to be quite potent *in vivo* following onion administration in canines (Briggs et al., 2000).

Significant applications also have been noted for the antimicrobial property of allium extracts, which extends to bacteria, fungi, and viruses; reductions in carcinogenesis; reductions in blood sugar and increases in insulin; and general antioxidant activity (Lawson, 1998). For many of these properties the thiosulfates have been implicated as the suspected causal agents, although much work is required to determine the involvement of other compounds with significant potential for biological activity. One such example is the flavonoids, which are present in high concentrations in colored onion tissues and have significant potential as antioxidants, show reductions in tumorigenesis, and remain at relatively high levels following thermal processing. Among the most prominent flavonoid in onions is the flavonol known as quercetin, which has shown great promise as an *in vivo* antioxidant and platelet inhibitor but less promising results when studied *in vivo* (Janssen et al., 1998).

It is important that the conversion of the ACSOs into thiosulfates is enzymatically controlled. Therefore this reaction may be significantly hindered by cooking. Furthermore the thiosulfates are volatile compounds that are likely altered and possibly reduced in concentration with thermal processing. For these reasons evaluation of the above-mentioned medicinal properties in feeding studies with cooked alliums are important in determining the extent of the health implications of dietary alliums.

### Nutritional Components and Utilization

The dry matter content of many allium vegetables is in the range of 7 to 15 percent, with the exception of the 35 to 50 percent dry matter found in garlic (Brewster, 1994). Approximately 1 to 2 percent is protein, 0.2 percent is fat, and 5 to 12 percent is carbohydrates. Garlic bulbs may contain up to 6 percent protein. The caloric value is approximately 35 calories per 100 grams but is much higher for garlic. Onion contains a variety of secondary compounds, such as flavonols, anthocyanin pigments, sterols, and saponins (Brewster, 1994).

Just as in ancient times, onion growing is still a specialized branch of farming. This onion farmer in Costa Rica is grading the onions in her barn. © CARL & ANN PURCELL/CORBIS.

A large number of processed products are made from vegetable alliums, and these find their way into a wide array of processed foods. Concentrated oils are produced from steam distillation of fresh onion and garlic, and these are used to deliver onion or garlic flavor to processed foods. Dehydrated products make up a sizable portion of the onion and garlic processing industry. Dehydration requires fairly low temperatures due to the potential for caramelization under high heat. The fresh product is ultimately dried to 4 percent moisture. The resultant dried flakes can be further ground into powder and mixed with salt and calcium stearate to produce onion or garlic salt. In a number of countries, particularly in Asia, pickled allium bulbs are consumed. These are produced in a fermentation process and then bottled in vinegar and salt to make a sour pickle or vinegar and sugar to make a sweet pickle.

During the late twentieth century the popularity of mild, sweet onion bulbs rose dramatically in many markets around the world, indicating a desire for a less-pungent onion. Reduced pungency can be obtained

through a combination of genetic backgrounds and favorable environments, in particular those soils where sulfur supply is low or is deliberately reduced. As discussed above, since the flavor pathway in alliums begins with the uptake of sulfate, high levels of soil sulfur can result in the production of more pungent onion bulbs (Randle et al., 1995). Only certain short-day onion cultivars grown in the southern United States have made significant inroads into the consumer market as a sweet or mild product, and these are not available year round in many markets. Since the accumulation and partitioning of sulfur and organosulfur compounds in alliums is not fully understood, it is difficult to predict the potential for mild onion cultivars in other market classes.

**ORGANIC AGRICULTURE.** Organic agriculture originated as a response to a growing awareness that the health of the land is linked to the health and future of the people. It is a holistic and philosophical approach to agriculture, which has as its goals the protection and conservation of the land for future generations, the production of high-quality food, the return to many traditional agricultural methods, and the harmonious balance with a complex series of ecosystems. Land, water, plants, animals, and people are all seen as interlinked and interdependent.

#### Definition

The final rule of the United States Department of Agriculture (USDA), which implements the Organic Foods Production Act of 1990, describes organic production as one which will "respond to site-specific conditions by integrating cultural, biological and mechanical practices that foster cycling of resources, promote ecological balance and conserve biodiversity." Organic agriculture promotes linkages and connections between land and water, plants and people. Soil fertility is enhanced through the use of composted waste to be generated at the farm site and recycled into it, multiple crops and rotations, a belief in the beneficial results of encouraging biodiversity through numerous species, and no use of synthetic fertilizers or pesticides. Further, stringent inspections, record keeping, and certifications are required to verify and maintain the organic status of the land and the food produced.

The terms "alternative," "sustainable," and "ecological" agriculture are also sometimes used, in place of organic, although not everyone believes that these terms are interchangeable. The European Union protects three terms: "organic," "ecological," and "biological" and abbreviations like "bio" and "eco" in all European Union languages. This is to prevent their use in a misleading or false manner. In the United States, the definition of organic agriculture by the National Organic Standards

Board is “an ecological production management system that promotes and enhances biodiversity, biological cycles and soil biological activity. It is based on the minimal use of off-farm inputs and on management practices that restore, maintain, and enhance ecological harmony.”

Today, organic agriculture is practiced in almost every country in the world, and the amount of certified organic land is growing as well. The total area is more than 42 million acres worldwide. The bulk of the organic land (45 percent) is in Oceania; Europe has 25 percent; North America, almost 8 percent; and Latin America, 22 percent. The emphasis in organic agriculture is on sustainability, local resources, and the stewardship of the environment, as well as expanding its global impact beyond food supply and into ecological health. Economically, the International Trade Center estimates the world retail market for organic food and beverages increased from \$10 billion in 1997 to \$17.5 billion in 2000. Revenue distribution by 2001 is estimated to be at 46 percent in Europe and 37 percent in the United States.

### History

At the beginning of the twentieth century, 39 percent of the United States population lived on farms, compared with less than 2 percent in 1990. Large land holdings were designed as federal lands to protect the natural environment and provide public access. Food quality, adequacy of supply, and public health were concerns. Issues with food quality led to the Pure Food and Drug Act of 1906. Extensive research was carried out to make plants disease resistant, and to improve yield. In the 1920s Rudolf Steiner, an extremely charismatic and complex individual, gave a series of eight lectures about agriculture that were the foundation of biodynamics, a concept in which all life forms and the land are in balance and combine with agriculture to address the health of the land with a spiritual dimension. By the 1930s hybrid seed corn had become common, and the devastation of the dust storms destroyed millions of acres of farmland in the Plains states. Two world wars had decimated farms and farmlands in much of Europe. Food supply for present and future populations was becoming a global concern. The vitality of the soil was seen by many as the key to a healthy future population.

Sir Albert Howard of England was one of the visionary leaders, if not the founder, of the organic agricultural movement in Europe. Philosophically, he linked the health of the land to the health of the people. Howard believed that agriculture as mainly practiced, with chemical fertilizers and a single crop, was out of balance with the environment and that many traditional agricultural practices should be revived. His major concern was for the health of the soil, which he felt could be maintained by a diversity of plant and animal crops, recycling of waste to enrich the soil, minimal depth in plowing, natural pest control, and smaller labor-intensive farms, emulating traditional methods.

Rows of parsnips, carrots, beets, and spinach are shown in these organic vegetable plots at Ryton, near Coventry, England.

© MICHAEL BOYS/CORBIS.

By the 1940s, chemical fertilizers and pesticide and insecticide use had increased. However, a USDA report from the same time warned that insecticides were present in food and advocated the use of naturally occurring products as insecticides. Some believed that conservation practices like cover crops, crop rotation, strip planting, and contouring of the planting were critical to preserve the soil both by keeping it in place and by maintaining its fertility. At the same time, conventional farming was stressing yields, mechanization, and modern practices. In 1949, official guidance was issued from the U.S. government on how to appraise the toxicity of chemicals in foods.

In America, J. I. Rodale had founded *Organic Gardening Magazine* and the Soil and Health Foundation (now the Rodale Institute). Many credit him from the mid-1940s onward with promoting and supporting organic agriculture in America. He went on to create numerous publications and with his research and publishing delivered his core message of “healthy soil = healthy food = healthy people.”

In 1959, the cranberry crop in the United States was recalled due to the presence of a cancer-causing chemical used to kill weeds. In 1962, Rachel Carson’s work

*Silent Spring* had a massive impact: Many Americans, for the first time, saw the link between the loss of plant and animal populations and the use of pesticides. By that time organic farming was well established as an alternative approach. Further environmental activism in the 1970s made many aware of organic agriculture and organic foods.

Alice Waters opened her restaurant Chez Panisse in Berkeley in 1971 and has been a promoter and champion of quality ingredients, supporting growers who farm organically. Her influence in turn promoted and sustained many other organic growers. The fame and growing impact of Chez Panisse have affected chefs and the public alike. Numerous chefs today provide details about ingredients on their menu, and many base their entire approach to food on organic products.

Likewise, vegetarians have long focused on the quality of the ingredients in their diet. John and Karen Hess in their landmark book *The Taste of America* decried the quality of food in America in the 1970s, stating that “[t]he health food and organic movements and the counterculture generally, have made some small but enormously promising steps toward reviving the taste of our food. . . . They are our hope” (p. 298). Organic agriculture has slowly grown, spurred by various scares but hampered by the counterculture label. Reports and findings in the 1990s with regard to the effect of pesticides and chemicals in food on humans, particularly children (for example, the use of alar on apples), drove the increasing demand for organically produced food, which in turn spurred the growth of organic farms.

### Application of Principles

Although many people associate organic agriculture primarily with fruits and vegetables, organic agricultural practices are applied effectively to all crops and animals. All crops—grains, citrus, nuts, fruits, herbs, vegetables, oilseeds like flax and sunflower, beans, cotton, grasses for pastureland—can reinforce a basic organic tenet: grow a variety of crops in a rotation system. Many people prefer organic agriculture because of its systemic approach that ties food production to ecology, and connects land, people, plants, and animals to a common goal, a healthy vital environment for all. Food produced organically is thought to be more flavorful, have higher nutritional values, be safer to eat, and be ecologically sound. Each food safety crisis, environmental scare, and dietary concern has increased the steadily growing pool of organic farmers and consumers.

The founders of the organic agricultural movement—Rodale, Balfour, and Howard, to name a few—passionately shared the belief that the health and vitality of the soil were key to the future of the land and food production. A fundamental principle of organic agriculture is that no synthetic fertilizers or pesticides are permitted. Complex ecosystems that encourage a rich diversity of plants, animals, and insects are considered

necessary for a viable and living soil. Composting, worms and beneficial insects in the environment, recycled farm wastes, use of manures, composts, ash, and crop residues contribute to the vitality of the soil, which in turn leads to healthy plants and animals. Further, organic agriculture addresses the broader environmental issues of pesticide and fertilizer residues, run-offs, and concentrations, which affect, not just the health of the organic farm system, but the ecosystems around it. The concept of balance between nature and human actions and stewardship of the land is integral to organic agriculture; in fact, it cannot be maintained otherwise. The inspection process leading to organic certification usually requires a minimum of three years in the United States (two years in the United Kingdom) to allow all traces of past land use practices to disappear. The first usable harvest follows the third year, assuming all other criteria are met for organic certification. This sizable commitment of resources is economically difficult and is one reason that many countries, although not the United States, have subsidies to help farmers certify their land for organic production.

Many feel strongly that organic foods, which are grown without synthetic pesticides, eliminate the concern for ingesting the residues or additives.

### Organic Foods

Most consumers believe, and some studies have shown, that there are more nutrients and flavor in organic products. Generally, organic products are more costly than foods grown by conventional agriculture. They are more labor intensive and must meet much stricter regulation, and therefore the cost of organic foods reflects the cost of production. Organic agricultural practices, which utilize local resources and eliminate outside needs as much as possible, fit developing countries’ needs very well as well as countries with food supply issues, for example, Cuba.

Cuba is considered one of the success stories of organic agriculture. Heavily dependent upon the Soviets for food and agricultural support, the collapse of the former USSR in 1989 left Cuba desperate for food. Overnight, supplies of synthetic fertilizers and pesticides and mechanized equipment all disappeared. Urban spaces were turned into gardens, plot sizes decreased, and organic practices were followed, as there was no alternative. The results have been dramatic, both in creating a new career for many and dramatically changing both the diet of the population and the appearance of Cuba. Now many people have access to fresh organic foods and unused land is turned to food production. Over one-half million tons of food were grown in Havana alone in 1998.

Before the 1990 Organic Foods Production Act, Title XXI of the Food, Agriculture, Conservation, and Trade Act of 1990, many state and other organizations certified organic production. The 1990 rules, published in December of 2000 after a decade in development, review, and revisions, set national standards for certifica-

tion of agricultural products as organic. Certification for all but the smallest growers and compliance for all agricultural products sold under these standards must be completed by late 2002. Certain practices and types of substances, like synthetic fertilizers and pesticides, are prohibited. The use of the word "organic" is now nationally regulated. In the United States, a raw or processed product labeled "100 percent organic" must contain only organic ingredients, although it can contain water and salt; if labeled "organic" it must be at least 95 percent organic and if labeled "made with organic ingredients" it must have at least 70 percent organic ingredients. Both the "100 percent organic" and "organic" designations can use an approved "USDA Organic" seal and penalties can be levied if there is any deliberate misrepresentation.

### Land under Organic Cultivation

In 1997, 1.3 million acres in forty-nine states were certified organic, and although this number had more than doubled in the 1990s, certified organic land still represents just 0.2 percent of all cultivated land (828 million acres). These totals include crop, range, and pasture lands. All indicators are that the amount of certified organic land is increasing rapidly, however. For example, in California, certified organic acreage increased by 38 percent between 1995 and 1997 and in Washington it increased by 150 percent between 1997 and 1999. The highest production crops that are certified organic are corn and wheat, although thirty-five states are producing a variety of certified organic grains. Tomatoes, lettuce, and carrots are the primary organic vegetables, with about 48,227 acres in organic vegetable production (in 1997); grapes produced on 39 percent of the acreage and apples on 18 percent of the certified organic farm land account for about 2 percent of the certified land that is devoted to producing these crops. Organic herbs are grown in thirty-two states; three states have certified specific land for harvesting wild herbs.

Prior to this national legislation for organic certification, organic land certification was given by over 40 organizations, which included twelve state programs. For example, California grew almost half of all certified organic vegetables in 1997; vegetable farming in Vermont, which has been promoting organics for 30 years, was 24 percent organic. Many states have started to develop incentives for organic conversion.

### Sales

Most organic farms are about one-third the size of the conventional farm and average about 140 acres. Organic vegetables are generally grown on even smaller holdings, with the majority less than 10 acres in size. They are frequently marketed directly to the consumer primarily through farmers' markets and restaurant chefs, accounting for 3 percent of total organic sales. A very popular form of direct marketing is subscription farming, some-

times known as CSA, an innovative way of connecting the consumer directly with the farm and crop. In 1998, there were 2,746 farmers' markets operating in the United States. Natural food stores, long a source for all organic products, recorded sales of \$4 billion in 1999, and an annual sales growth rate of at least 20 percent. Total retail sales of all organic products are estimated at \$7.8 billion in 2000, and \$833 million of fresh organic fruits and vegetables were sold in natural food stores in 1999.

### Organic Agriculture Worldwide

On a global level, in Europe, Japan, the United States, and the United Kingdom, retail organic food and beverage sales accounted for about 2 percent of the total, about \$13 billion in 1998, with an anticipated annual growth rate of 20 percent.

In 2001, Canada reported of 246,923 farms, 2,230 produced certified organic products, and 614 of these, or 27.5 percent, produced fruits, vegetables, or greenhouse products. Nearly fifteen hundred farms, or 64.7 percent, reported organic field crops. In Canada, the formation of the Land Fellowship in Ontario in the 1950s provided the foundation of the organic farming movement. As in the United States, these early visionaries were joined in the 1970s by a host of individuals and organizations whose concerns for the environmental health of the planet made an immediate linkage to the principles of organic agriculture. Numerous organizations, like the Canadian Organic Advisory Board, which is composed of volunteers, promote and support organic agriculture in a variety of ways throughout the provinces. Canada's National Standard for Organic Agriculture is a voluntary standard for organic production, whose principles and practices focus on protection of environmental biodiversity, a comprehensive and systematic use of organic practices for the production of foods, and a verification process to ensure the standards are met.

Sir Albert Howard is not the only founder of the early organic movement in the United Kingdom to have a global impact. Lord Walter Northbourne is credited with creating the phrase "organic farming" in his 1940 book *Look to the Land*, and Lady Evelyn Balfour, whose book *The Living Soil* was based on years of comparative farming data, inspired many to support the principles of organic agriculture put forward by Howard. Lady Balfour was also involved in the founding of the Soil Association in the United Kingdom in 1946. The Soil Association remains an active advocacy group for organic standards. Throughout the United Kingdom, there is a wide range of organizations, government ministries, colleges, and research centers focused on research, education, advocacy, and sustaining organic agricultural practices. The first organic standards were published by the Soil Association. The group performs the majority of the inspections, although several other approved inspection groups also perform certification inspections.

In the United Kingdom there were 2,865 licensed organic farmers in production, or in conversion, in 2000, a dramatic increase from the 828 listed in 1997. In late 1999, 2 percent of all agricultural land (a little over 1 million acres) was farmed organically (fully organic or in conversion). Organic vegetable production value for 1999 was \$28.8 million in the United Kingdom. Nearly half of the consumers interviewed said they bought organic produce for the taste.

The Food and Agricultural Organization of the United Nations (FAO) has published the *Codex Alimentarius* to establish global food standards and guidelines for organically produced foods. The FAO states:

Foods should only refer to organic production methods if they come from an organic farm system employing management practices which seek to nurture ecosystems which achieve sustainable productivity and provide weed, pest and disease control through a diverse mix of mutually dependent life forms, recycling plant and animal residues, crop selection and rotation, water management, tillage, and cultivation. Soil fertility is maintained and enhanced by a system which optimizes soil biological activity and the physical and mineral nature of the soil as the means to provide a balanced nutrient supply for plant and animal life as well as to conserve soil resources. Production should be sustainable with the recycling of plant nutrients as an essential part of the fertilizing strategy. Pest and disease management is attained by means of the encouragement of a balanced host/predator relationship, augmentation of beneficial insect populations, biological and cultural control and mechanical removal of pests and affected plant parts.

In Europe, the European Union countries have a total of 10 million acres held in 145,113 organic farms, which represent about 2 percent of farms and about 3 percent of the farming acreage. This figure represents a rapid rate of growth, about 25 percent over the last ten years in European Union member countries. For example, as of 2001, France had over 10,000 organic farms, an increase of 12 percent from the previous year. Ongoing research in organic agriculture is being conducted in most countries, and some have adopted educational programs that support the organic farmers as well as the consumers. Uniformity of standards and dissemination of research are critical to the future of organic agriculture. The International Federation of Organic Agriculture Movements (IFOAM) was founded in 1972 to coordinate research and represent organic agriculture worldwide in forums for policy and law. Currently, IFOAM is working in 100 countries with more than 690 member organizations. Perhaps most important, it sets, maintains, and revises the IFOAM Basic Standards of Organic Agriculture and Food Processing, which are translated into eighteen languages and ensure the quality of and equal application of the organic certification through the IFOAM Accreditation Programme.

## ORGANIC FARMING AND GARDENING.

Organic farming is the practice of growing crops and livestock without applying any synthetic products such as inorganic fertilizers, growth hormones, genetically modified organisms, or pesticides. In contrast, the modern practice of growing crops that relies largely on the use of synthetic (human-made) products is termed “conventional” agriculture. Organic farming not only consists of using a different set of production tools to grow crops, but its philosophical approach to farming also differs from that used by “conventional” farmers. In general, organic farmers intend to establish a production system that works with nature instead of one that dominates nature. For instance, organic farmers strive to maximize natural nutrient cycles that mimic those found in natural ecosystems. Similarly, organic farmers strive to exploit natural pest control mechanisms, such as biological controls, which are also typical of natural ecosystems. In contrast, conventional growers rely on capital- and energy-intensive production methods, such as those that use inorganic fertilizers and pesticides, to overcome problems of poor soil fertility or to manage the outbreak of damaging pests and diseases.

### History

The organic farming movement was born in the twentieth century as a response to the concerns of some agricultural ecologists that so-called conventional farming practices were causing environmental harm, and that in the long term were basically unsustainable. Concerns that organic farming practitioners have with conventional farming include contamination of ground waters with fertilizers and pesticides, loss of genetic crop diversity, eutrophication of aquatic habitats, and depletion of soil fertility. Organic farming proponents used production techniques that built upon those long used by traditional farmers prior to the discovery of agricultural chemicals. In fact, even today, millions of small farmers in the developing world continue to follow chemical-free production techniques. Most of these subsistence farmers, located in tropical areas, follow chemical-free practices by default, because they lack the capital or access to relatively

## DEFINITIONS

**Eutrophication.** Oxygen depletion in aquatic habitats due to excessive nutrient leaching (especially phosphorus) from agricultural runoff, resulting in the death of aquatic biota.

**Community supported agriculture** (or CSA; also termed subscription farming). Members of the community purchase “shares” from local growers, “investing” in the current production season, and thereby sharing in both the risk and bounty of agriculture. Produce from the farm is distributed to members on a weekly basis during the harvest season.

**Soil quality.** In general terms soil quality refers to a combined number of physical and biological soil attributes that result in optimal crop growth. The particular attributes that affect soil quality may vary across locations and by the crop being grown. Some traits that promote soil quality include high organic matter content, good texture, no compaction, good drainage, optimal temperature, and a deep soil profile.

**Natural enemies, or beneficials.** The typical farm is a host to a wide number and diversity of macro- and microorganisms living both above and below ground. Only a very small percentage of these organisms is considered harmful to crop growth—and thus categorized as a pest. Organisms in the soil or in the plant canopy that feed on, or that in some way antagonize, crop pests are called natural enemies or “beneficial” organisms.

**Organic certification guidelines.** Written guidelines have been established for growing crops organically in many parts of the world. Farms that follow these guidelines can become certified, which allows farmers to label their products as organic in the marketplace. Federal organic standards in the United States will facilitate the global expansion and consumer awareness of this growing eco-industry.

expensive synthetic products. In the developed world, organic farming increased rapidly in popularity in Europe, Japan, Oceania, and the United States, beginning in the second half of the twentieth century. Even though organic farms still represent less than 5 percent of all the agricultural acreage, their popularity continues to increase in both developed and developing countries. Despite the fact that the acreage under organic farming is rapidly increasing, to date the demand for organic produce has actually outpaced the available supply. Because of the real

### CULTURAL PRACTICES TYPICAL OF ORGANIC FARMING

- Increased soil organic matter through organic amendment applications
- Rotations
- Use of cover crops and green manures to break pest and disease cycles and to improve soil fertility
- Increased vegetational diversity
- Enhanced biological control
- Alternative marketing techniques such as Community Supported Agriculture or direct marketing to health-food stores.
- Use of organic fertilizers and organic pesticides approved by the Federal Organic Standards list of approved products.

or perceived safety of organic produce, the appeal and demand for organic products are expected to continue to increase exponentially in the foreseeable future.

Organic farmers normally undergo a rigorous on-farm certification process before they can label their products as organic. This process, created to protect the consumer, simply certifies the production process, but the organic label itself makes no claims as to the safety or chemical composition of the labeled product. The recently established federal organic standards in the United States, and similar standards already established worldwide, will further facilitate the expansion and trade of organic products on a global basis.

#### Production Practices

One of the fundamental principles of organic farming is the goal to maintain and improve soil quality. Proponents believe that having a healthy soil is the basis for having a sound crop production system. According to this perspective, crops grown on healthy soils will grow faster, will better tolerate or resist pests and diseases, will have better quality, and will result in adequate yields, year after year. Important tactics to improve soil quality include increasing the organic matter content of the soil, crop rotations, and growing a diversity of crops on the farm. Organic matter is added to the soil by applying composts, using organic mulches, or by growing cover crops as part of the crop rotation program. If the soil suffers from a nutrient imbalance or lacks a particular nutrient, this can be rectified by applying accepted natural materials such as lime, rock phosphate, or sulfur. A healthy soil is also believed to result in crops that better resist or outgrow

pest invasions. Other important cultural practices used to minimize pest attack include crop rotations, field sanitation, planting resistant varieties or cultivars, crop diversification, and the conservation of natural enemies. When pest outbreaks occur, as a last resort, organic farmers may apply naturally occurring pesticides (such as sulfur), use botanicals, release beneficials purchased from a commercial supplier, or use other tactics approved by the organic certification guidelines.

Historically, organic farmers have received little support from established research universities, as the overall research focus to date has been to increase yields of conventionally grown crops. However, as the demand for organic products continues to increase worldwide, more and more research resources are gradually being devoted toward improving organic systems. Thus, in the foreseeable future, research will improve our knowledge of how organic systems function, revealing new alternative methods to maintain long-term fertility of the soil, and ways to manage important pests and diseases.

#### Risks and Benefits of Organic Farming

Farmers throughout the world have adopted organic farming mainly because of a concern about the environment, to protect the health of the family farm and its hired labor, and with the goal of marketing crops that are free of pesticide residues or genetically modified products. However, the label of an organically certified crop only makes claims about the production process, and not about the quality or nutritional composition of the crop being sold. While organic produce sold in the marketplace is, for the most part, considered safe for human consumption, critics point out that organic produce may pose a health risk due to the possible presence of biological contaminants (such as *E. coli*), or toxic botanical pesticides. Other real or perceived problems with organic farming include a higher cost of production, lower relative yields, lower quality due to a greater incidence of blemishes in the produce caused by insects and diseases, and the general lack of technical information currently available to manage large-scale organic production systems to supply a large consumer base with high-quality produce on a year-round basis.

#### Future Trends and Opportunities

The organic farming industry is currently undergoing a fast transformation from a relatively small niche market, into a part of the mainstream global produce production and distribution system. As the demand for organic produce continues to increase at about 20 percent annually, the supply cannot currently keep up with the growing demand. As the size of the organic industry grows and as the international markets develop, the industry will grow in sophistication from a production and marketing standpoint to meet the quality and service standards expected by consumers. Thus, the organic industry will need the support of universities and government agencies to con-

tinue to develop the technological know-how and marketing infrastructure needed to establish a dynamic and competitive world-class organic produce industry.

**ORGANIC FOOD.** Organic food refers to crops or livestock that are grown on the farm without the application of synthetic fertilizers or pesticides, and without using genetically modified organisms. In contrast, the type of agriculture followed by most farmers, which does include the use of synthetic pesticides and fertilizers, is termed “conventional” agriculture. In 2002, with a value in the United States of over \$4 billion, organic foods still represent only a small segment of the entire food industry. However, since the early 1980s the organic food industry has increased considerably both in the acreage devoted to grow organic products and in its popularity with the general public.

Consumer surveys indicate that the public is concerned about the safety of the produce that they purchase in stores due to possible pesticide contamination. The media has also highlighted some environmental concerns that exist with “conventional” farming. These environmental concerns include pollution of aquatic habitats and aquifers by synthetic fertilizers and pesticides; agricultural labor and consumer exposure to pesticides; the short-term approach to “conventional” farming, which often results

in unproductive unfertile soils a few years after intensive use of the land; the loss of biological diversity by replacing natural landscapes with extensive monocultures (the practice of growing the same crop, on the same location, year after year); the potential threats to native habitats and wild species from contamination by genetically modified organisms; and the displacement of the family farm by large plantations or corporate-style farming operations. The list of real or perceived health and environmental problems that exist with conventional farming, has in part, contributed to the increased popularity among the general public of organically produced food.

During the 1990s the U.S. organic food industry grew at a fast pace of over 20 percent annually. Because the supply has not been able to keep up with the high demand, organic food normally commands a premium price, compared to conventional food. Thus, organic farming is an attractive proposition for both established and new farmers concerned about human health and about the environment, and also because of the premium price obtained from selling organic produce in several countries.

#### History of the Organic Movement

The organic farming movement was born in the early twentieth century as a response to the concern that some agricultural ecologists had with conventional agriculture. Early critics of conventional agriculture and organic farming proponents included agricultural ecologists such as Sir Albert Howard in both England and India, and Scott Nearing and J. I. Rodale in the United States. For conventional agriculture, they claimed, short-term profits took a precedence over the environment, resulting in rapid degradation of fertile agricultural lands. From their perspective, the excessive reliance on external inputs such as fertilizers and pesticides, and continuous monocultures, antagonized the natural nutrient cycles and pest suppression mechanisms that exist in natural ecosystems. They proposed and developed production systems that precluded the use of synthetic external inputs, and substituted them with alternative production methods, only allowing the use of naturally available amendments such as composted animal manures, botanical pesticides, and the use of green manures (a cover crop, such as clover, that protects the soil from erosion and is subsequently turned under to amend the soil). Early organic production techniques were actually built upon production practices that were originally used by subsistence farmers throughout the world before the discovery of synthetic fertilizers and pesticides. These early farmers, over millennia, developed farming systems that worked closely with nature, resulting in a finely tuned system that periodically “regenerated” itself from an ecological standpoint, and thus ensured that the land would remain healthy and productive indefinitely. From the early twentieth century, organic farmers have continued to promote those well-tested techniques used originally by subsistence farmers,

This cereal was produced organically in England and has been certified as organic on the side of the box shown here. © IAN HARWOOD; ECOSCENE/CORBIS.

and have continued to modify and perfect them, and to introduce new innovative techniques as they learn more through research and experience.

From a production standpoint, the heart of organic farming is considered to be a healthy soil. Organic farmers consider the soil to be a living entity that needs to be cared for and nurtured. Furthermore, they claim, many of the ailments that today's farmers encounter in the field, in terms of nutritional problems or pest damage on their crops, is nothing but a symptom of an unhealthy soil. Modern research has actually substantiated that all aspects of the production system of the farm are interrelated. Some studies have found links between soil quality and pest, weed, or disease outbreaks. Key tactics used by organic farmers to improve soil quality include incorporation of organic amendments such as composts; the use of organic mulches, which also serve to smother weed growth and retain moisture; and the use of cover crops or green manures, which are incorporated into the soil after reaching a particular stage of growth. If the soil suffers from a nutrient imbalance or lacks a particular nutrient, this can be rectified by applying accepted natural materials such as lime, rock phosphate, or sulfur. Today, organic farmers can monitor the quality of their soils, not only by observing how well their crops are growing, but also by having their soils analyzed by certified diagnostic chemical laboratories.

Crop losses from pest attack can be one of the primary production problems for a farmer. Organic farmers believe that a healthy soil rich in organic matter will

result in a balanced system that allows crops to better resist or outgrow pest invasions. The farmer's goal, concerning management of pests in the organic farm, is to establish a balanced system, in which pests and diseases are kept in check through natural pest suppression mechanisms, including the activity of natural enemies. Natural enemies are macro- or microorganisms that act as predators or parasites to reduce pest populations. Populations of natural enemies can be promoted in the farm through crop diversification, including intercropping, and by growing a diversity of crops concurrently on the farm. Other important cultural practices used to minimize pest attack include crop rotations, field sanitation, and planting resistant varieties. When pest outbreaks occur, as a last resort, organic farmers may apply naturally occurring pesticides (such as sulfur) and botanicals, release beneficials purchased from a commercial supplier, or use other tactics approved by organic certification guidelines.

### The Organic Certification Process

Because the organic food industry is relatively small and new, it is important that consumers become aware of its claims, limitations, and potential benefits. In order to better protect the consumer, organic certification programs were created in many parts of the world to develop a label for organic food. An organic certification label makes a claim as to the production process used to grow a crop, but the label makes no claims concerning either the quality or the chemical composition of the product itself. Thus, an organic label does not claim that a particular product is more nutritious, pesticide-free, or tastier—it only indicates that the product was grown following a defined set of organic practices as certified by an accredited state, federal, or international certifying agency.

As the organic food industry grows in size, popularity, and value, its products are increasingly traded across national borders and continents, as it joins the global food trade market. To further the national and international expansion of this industry, and the ability of local growers to export organic products, the United States published a set of federal organic production standards in early 2001. The new federal organic standards will cover the entire country, and replace the guidelines previously used by independent or state agencies in various parts of the country. Because a similar area-wide certification program also exists in Europe and in other regions, it will become easier in the future to trade organic products across borders. In the end, the certification process results in an organic label in every item sold as organic, and this label assures the consumer that this product was produced following a strict set of standards that are uniform across the United States, and similar to those followed in other parts of the world.

The process to certify a farm as organic is a rather rigorous task that involves a lot of planning, good management, and record-keeping. Farmers rely on published organic certification guidelines to find out what practices

are acceptable and what products are allowed for use on the farm. For land to be certified as organic, no synthetic fertilizers or pesticides can be applied to it for three years prior to certification. Part of the application process involves a detailed plan provided by the farmer that describes the entire operation, with a focus on what organic techniques will be used to produce and market crops in the farm. If the original fertility of the soil is deficient, the plans detail what will be done to rectify this problem. The certification process also includes taking soil samples to evaluate soil fertility and to detect the possible presence of any unacceptable pesticides in the soil. To ensure that the farm remains in compliance, organic inspectors will visit the farm annually. The record-keeping maintained by the farm helps the inspector to double-check that the farm operations are being conducted as indicated in the original farm plans.

### **Risks and Benefits of Organic Foods**

Currently, organic products are sold at premium prices in an ever-increasing number of stores, and increasingly compete for shelf space with conventionally grown produce in supermarkets. Reasons for the premium prices obtained for organic products include that they are grown without pesticides and thus may be more expensive to produce because of the added labor; because they are grown in a way that does minimal harm to the environment; because no genetically modified organisms are used in the production process; because of a perception that they are better tasting; and also because the produce may have been grown locally and the consumer wishes to support small family farms. Because conventionally grown products are often bred to withstand shipping and to withstand a long shelf life after harvest, often at the expense of flavor, consumers often prefer to purchase tastier varieties, grown locally under organic conditions. However, consumers should be aware that exceptions may occur, and that in some instances conventionally grown products may actually be more nutritious, tastier, and grown in ways that minimized damage to the environment. Also, in some instances some organic farms may not be managed correctly, resulting in environmental problems such as excess erosion. Botanical pesticides, even though they are “natural,” should also be evaluated for their risk to humans, wildlife, and the environment. Similarly, improper handling of organic produce after harvest may result in product contamination and in food-borne illnesses. Thus, it is important that the consumer becomes educated about both the benefits and possible risks of purchasing either conventional or organic products, so that better decisions can be made about what products to buy, and whether it pays to invest in products with a premium price.

### **Current Trends for Organic Foods**

Because of its popularity, the organic industry grew at a fast pace since the mid-1980s. Throughout the 1990s in the United States, the organic industry grew by 20 per-

cent annually. Similar trends were observed in regions where affluent and educated consumers support environmentally sound production programs, small family farms, locally grown produce, and products free of pesticide residues or bioengineered materials. Thus the organic industry has also grown in Europe, Japan, New Zealand, and Australia, sometimes at a faster pace than in the United States. However, questions exist as to the future expansion of the industry. Even though many conventional farmers are interested in converting to organic production, this process becomes more difficult as the area under production increases. As the area of production increases significantly, from farming only a few acres, into farming hundreds of acres, problems of soil fertility or pest outbreaks become more difficult to manage with organic techniques. This lack of appropriate technology is explained in part because in the past little formal research was conducted by universities to support organic farmers. During the twentieth century, most agricultural researchers were busy supporting an agricultural system that relied on the use of expensive synthetic chemicals. Thus, considerable research support will be necessary in the future to develop production techniques that will allow for the successful production of organic crops on a wider scale than is possible today. Considerable consumer support will also be necessary to facilitate the expansion of the organic industry. Better informed consumers may learn to accept products with minor blemishes, realizing that the minor defects do not affect taste or nutrition and that these products were grown without the use of toxic chemicals. Educated consumers may also be willing to pay a premium price for organic products, knowing that a large organic industry translates in the long term into a healthier environment with cleaner lakes and rivers and potable aquifers.

If the organic farming movement is to expand the area under cultivation and into other countries, the industry will have to grow in sophistication, to establish a seamless delivery system from the farm to the dinner table. The organic industry also will need to better educate the public about what organic farming is, and what it is not. The newly released national organic standards in the United States, and equivalent certification programs in Europe and elsewhere, will facilitate this process. Because the certification standards clearly delineate the entire production system, the public will be better assured of what they are purchasing when they see an organic label. Misconceptions about organic products will have to be overcome to build public trust in the industry. For example, proponents often claim that organic products are tastier and more nutritious than conventional products. While some isolated studies have indicated that in some cases organic food was more nutritious (more vitamins, etc.), this cannot be generalized to all crops and locations. On the other hand, contrary to some public perceptions, organic produce is not often infected with microbial contaminants, and the risk of food-borne illnesses from organic produce is minimal.

Thus, from the consumer's standpoint, there are several important reasons to purchase organic products. These include supporting the production of farm products that are grown in a manner that minimizes negative impacts on the environment; advocating a system that protects the health of the agricultural workers by minimizing their exposure to toxic chemicals; supporting a system that helps to maintain a rich wildlife in rural areas; and standing for an agricultural system that provides a fair price for the food that is purchased, thus allowing small organic farmers to lead independent, productive lives. A number of innovative marketing techniques bring urban consumers into closer contact with the land. One example of this trend is called Community Supported Agriculture (CSA), or subscription farming. With CSA, community members purchase "shares" of an organic farm—and thus help the farmer to purchase needed inputs prior to the production season. By doing this, the community shares the risk of crop losses that farmers face every season. As part of the program, the CSA farm distributes to its members products from the farm on a weekly basis, providing a bounty of fruits, vegetables, and often dairy products. The urban family members also visit the farm, sometimes to help with the harvest, once or more during the growing season. This type of marketing program helps bridge the wide gap that exists between urban and rural areas, and both parties benefit from this innovative arrangement. The urban families, especially children, learn about where their food comes from, allowing them to become better consumers, and to understand the impacts of agriculture on the environment. In turn, this symbiotic association allows the CSA farmer to become more savvy about the likes and dislikes of the urban consumer, allowing the farmer to modify and improve the farm's menu of products year after year.

**ORGANIZATIONS.** *See* **Government Agencies; International Agencies.**

**PACIFIC OCEAN SOCIETIES.** Oceania, the collective name for islands in the Pacific Ocean, consists of high volcanic islands, atolls, and two larger continental islands. On the volcanic and continental islands, the topography, climatic range, and rich soil allow a range of foods to be grown. On atolls, in contrast, the poor soil, shortage of fresh water, and exposure to salt spray restrict the plants that will grow. Fiji thus has a wider inventory of foods than the atolls of the Marshall Islands and Tuamotus. Increasing population size also places stresses on local plant foods.

The islands of the Pacific Ocean are surrounded by seas that cover half the surface of the globe. They have been settled over the last three thousand years by people who sailed east from Southeast Asia, carrying the planting material for taro, yam, and breadfruit, and possibly coconut. Later westward voyages from South America carried other plant stock, such as sweet potato, cassava, and *Xanthosoma taro*, that added to the biodiversity. The settlers on the various islands gradually developed autonomous groupings and discrete identities and languages, along with different food preferences. These Pacific island societies became subject to colonial control from the early nineteenth century until the 1960s, when each society sought independence on its own terms. Coconut and sugar cane became plantation crops, while coffee, cocoa, and other plants were introduced. With the development of a cash economy, imported foods such as rice, flour, and canned meat have played an increasing role in people's diets.

### **Staple Foods**

Root and tree crops are the starch staples of Pacific Ocean societies. These roots and edible fruits are usually eaten with fish, or, if none is available, then a piece of coconut. Several varieties of the root crops and tree starches have been developed in situ, so that Hawaiians had seventy-two different types of *Colocasia taro* that they used for food. Sago is another starchy tree crop that is widely used throughout New Guinea. The coconut tree provides nuts, the meat of which is a major accompaniment to any of these starches. Coconut juice is a pure beverage, and other parts of the tree are used in food preparation and other products. Rice imported from countries is a recent

and ubiquitous addition to the diet (Malolo et al., 1999; Pollock, 1992).

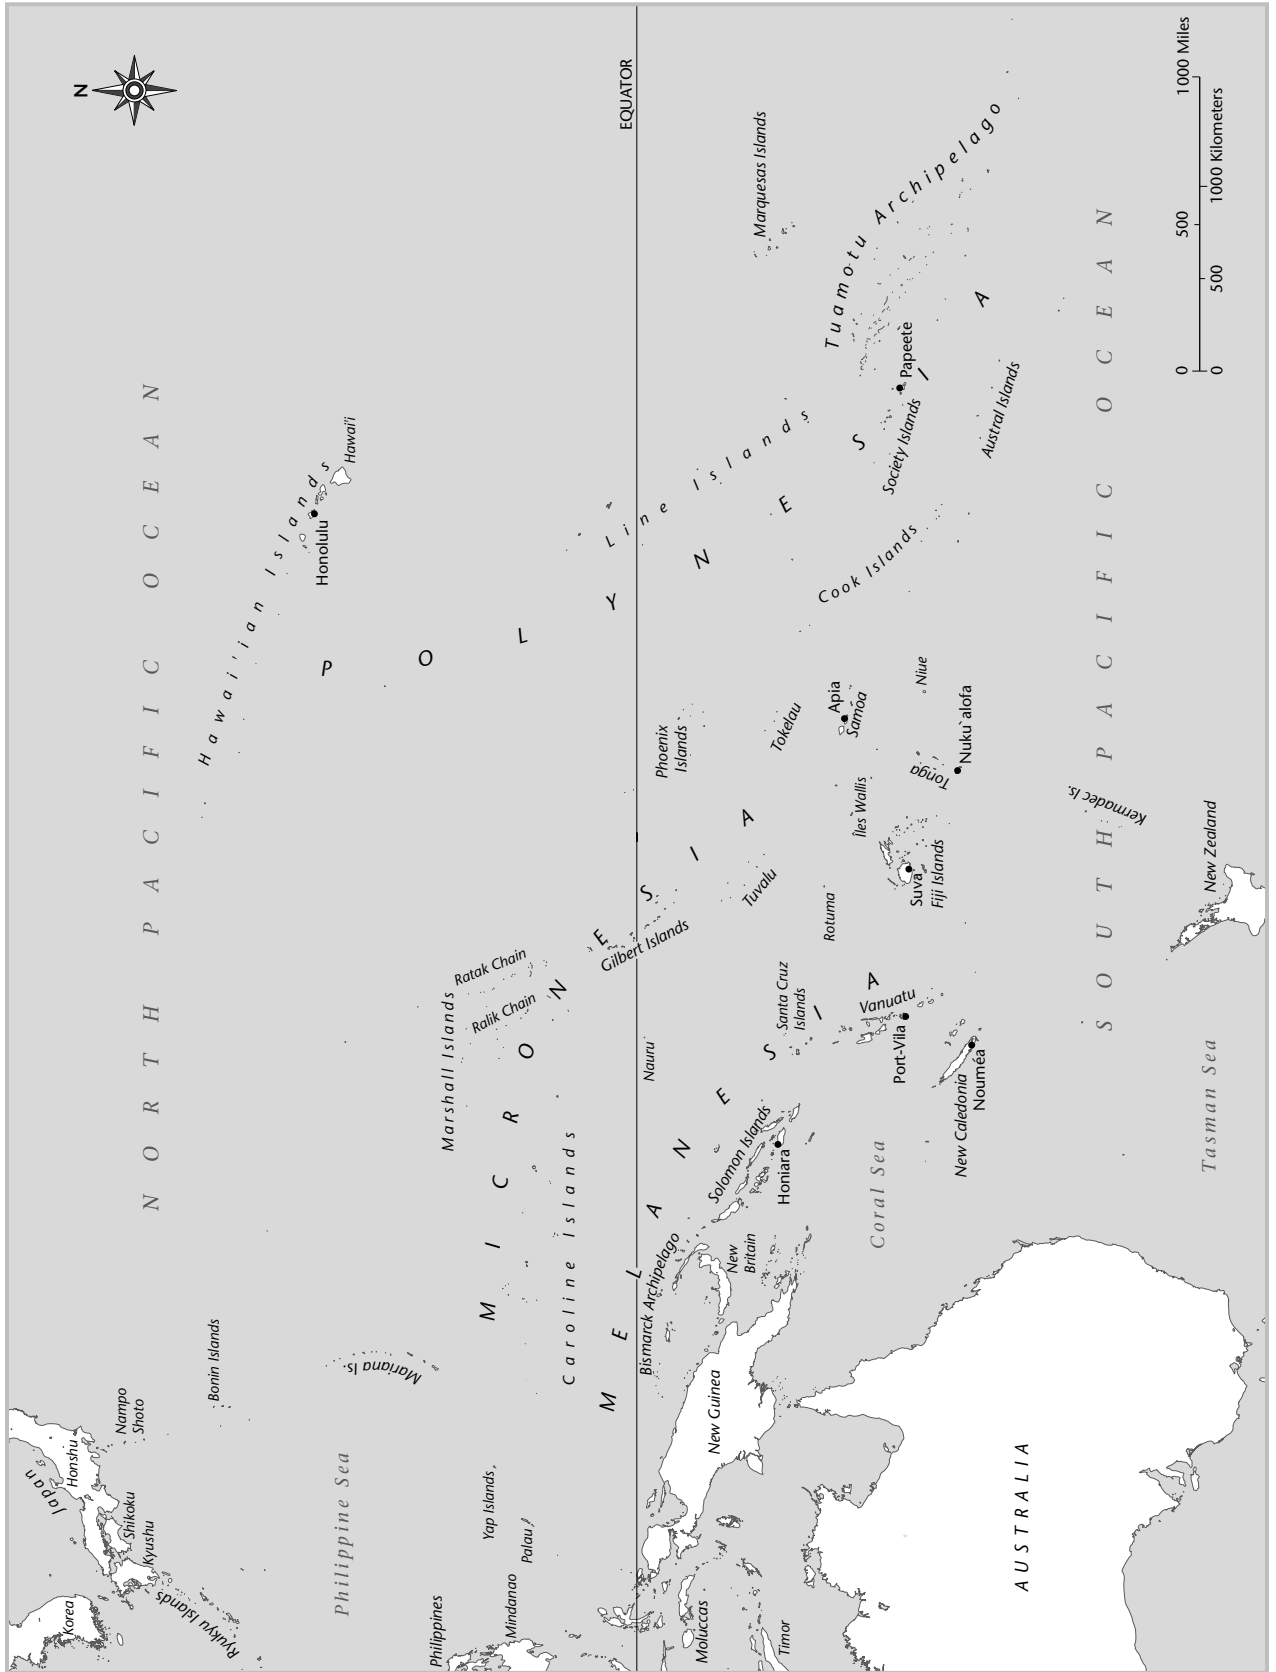

All these plants only reproduce vegetatively, so they had to be transported by people who knew their value. Over time many varieties have been selected for size of the root or fruits, extended seasonal availability, and reduced acidity. Taste has become more varied as fermented roots and fruits are either processed directly, or added to the fresh pulp, and then cooked. Cassava, sweet potato, and *Xanthosoma taro* (*Xanthosoma chamissonis*) have been added to the inventory, brought from the Americas. While widely accepted for household use, they have lesser status for ritual and ceremonial occasions. Taro and yam remain the major status foods for both household and ritual occasions (Pollock, 2002).

### **Diet and Nutrition**

These starchy foods make up the bulk of the diet, because "they make us feel full" (Leota, in Pollock and Dixon, 1997:72–75); in local languages they are termed "real food" (Fijian *kakana dina*). About 80 percent of daily intake comes from one or a combination of these starches (including rice) (Malolo et al., 1999). But the starchy food must be eaten with an accompaniment for people to say they have "eaten." That accompaniment may be a piece of coconut or fish, or shellfish, and is vital to the feeling of satisfaction from eating. Outsiders may term these two components a "meal," though that is a concept introduced from the West (Pollock, 2000).

Local starchy foods are high in energy, and they provide some protein, minerals, vitamins, and dietary fiber (Malolo et al., 1999, p. 11). The nutrient content of the foods generally consumed by peoples of the Pacific islands is considered good (Dignan et al., 1994). Some *Colocasia taro* varieties can have 7 grams of protein per 100 grams, while *Xanthosoma taro* has a high Vitamin C content. Cassava is high in energy/calories but low in protein so is best consumed along with other root crops. The major source of fat in the diet comes from coconut and fish, though fried doughnuts and chicken are recent delicacies that are eagerly consumed when available, mainly in towns.

The traditional diet was high in fiber but low in salt, fat and sugars. However, the introduced foods, such as

fried chicken, turkey tails, and soft drinks, have increased the amount of fat, salt, and sugar in the diet and are thus considered to be major contributors to health problems, notably diabetes, hypertension, and obesity (Coyne, 1984). The Pacific Islands Nutrition newsletter, which is distributed in all the island communities, stresses the links between diet, health, and lifestyle and suggests how diet can be improved (i.e., no. 43, March 2000).

Production of local starchy foods is diminishing as land is diverted to cash crops. Farmers can get a high price for their taros or yams when sold in the local market and in urban centers, but the returns from export crops such as sugar and ginger are better. Competition with low-priced imported foods, such as rice and flour, is a concern to nutritionists, since these imported starches have less nutritional value than the local starches. Local campaigns, such as that run by the Fiji Food and Nutrition Committee, have highlighted the attributes of local foods with an “Eat More Local Foods” slogan.

### Food Preparation and Eating Habits

The traditional manner of eating once a day, or perhaps only three or four times a week, has changed with Western ideology and practices. Early visitors to the Pacific islands decried the large amounts of food they saw being consumed at feasts, terming it “gourmandizing” or “gluttony.” They taught the people to regulate their food intake, that is, to eat at least once a day (Pollock, 2000). Today people eat two or three times a day.

That earlier pattern of irregular eating was well suited to the seasonal nature of the root and tree crops as well as to the organization of daily life. People ate what was available, and then waited until the next occasion when the roots and fruits had been harvested and cooked in the earth oven. But that pattern of gluttony and abstinence was deemed uncivilized by the early missionaries. The regularity of meals is one contributing factor to the obesity that is being recorded today (Pollock, 1995).

Cooking of the root and tree starches is essential to render them edible. The earth oven was the most ubiquitous form of cooking, but it has been largely replaced by quicker forms of cooking, such as frying and boiling. In the earth oven, the peeled starches together with fish, or pig for a feast, were placed on hot coals and covered for a couple of hours, so the food was steamed. Much of the cooking in Polynesia was young men’s work, with the women peeling the roots and fruits for the men to cook in the earth oven. Today women cook in the kitchen, using quicker processes, while the earth oven is used mainly for communitywide ceremonial feasts. The earth oven is more economical in the use of wood fuel, but the newer forms of cooking are a problem for those Pacific communities without access to electricity.

Fermented foods were in part a means of storing any excess but also a means of adding a distinct taste to the rather bland root and tree foods. At the end of the main

Men and boys in American Samoa prepare earth ovens for a large feast. © JACK FIELDS/CORBIS.

breadfruit season, the Marshallese (and other Pacific peoples) devised a system of placing the ripe breadfruit in a pit in the sand lined with leaves, where it fermented for a few months. The resulting paste, which is said to resemble cheese, could then be prepared either on its own, or mixed with some fresh breadfruit and baked as a loaf. These pits were a valuable means of storage for times when the breadfruit trees were decimated by hurricanes, or the taro pits were inundated by a tidal wave. In Hawaii, poi was an important product of fermented taro that was highly valued when eaten with fish. Food researchers have commercialized poi, as it has properties that make it suitable for sick babies, the elderly, and those suffering from grain crop allergies.

### Feasts

Feasts, an integral part of Pacific island life, are marked by a proliferation of foods, many prepared in more elaborate ways than the daily meal. These foods are generally referred to as “puddings” though they are unlikely to contain sugar. Whole fish, turtle, pork, and suckling pig (particularly in Tonga) form the centerpiece. Foods not eaten by those present at the feast are carried home to be shared with other household members. Traditionally, such feasts were the means of honoring a chief or important visitors. They still highlight important events, such as the coming of age of a Tongan princess. The feast is often part of a wider social display that is likely to include dancing, sports such as *krikiti* (cricket) in Samoa, and music.

### Problems of Food Security

Sharing food is a hallmark of Pacific Ocean societies and continues to be a major way of fostering a feeling of food security. Food has been and still is exchanged on a daily basis between households and communities. Brothers and sisters send food to their mother and father. Well-being is assessed in terms of types of food available, abundance,

and generosity toward extended family members and others. Such exchanges have contributed to the diversification of foodstuffs. They have evened out disparities so that no family should be shamed by failing to have enough to provide for others.

Imported food from outside the Pacific islands has increased markedly in the twentieth and twenty-first centuries. It adds further variety but only for those with the cash to buy those foods. Reliance on rice as a cheap everyday food is blamed for many of the nutritional and health problems now appearing for the first time in Pacific Ocean societies. Food poverty is a major concern noted in the Fiji Poverty Study (1996). Worst off are urban family households with only one income, which may have to feed some twelve or fifteen people. At the state level, governments have been trying to reduce the high proportion of food imports, which ranges between 12 and 35 percent of total imports. Support for local food producers is essential if the islands are to resolve the food crisis.

Food security is the key concern for the future. The gap between the food-poor and those with adequate food is increasing. Rice and tea or bread and tea may be all a family can provide on a daily basis if they have no land and little money. Weaning infants on sweet tea mixed in rice gives them a poor start in life. The problems of food security thus range from overeating to undereating: some island peoples consume too much fatty food and pop drinks, while many struggle to feed the growing numbers in their households.

Household food security has thus become a major concern for island peoples who until the 1960s had established a regime, both social and material, that met their needs. Today's needs are more complex and require complex solutions.

#### PACKAGING AND CANNING, HISTORY OF.

In preindustrial society, packaging of food was far from being unknown. It was used for food storage at home and for transport from the production place, the farm, or workshop to the local or regional market. Examples are the transport of cereals or flour in bags, tea in wooden boxes or tinplate canisters, and oils in jars. At the household level, people salted meat and pickled vegetables and preserved them in jars. In groceries at the end of the nineteenth century, most commodities were still unpacked and sold in bulk. Products such as tea, coffee, sugar, flour, or dried fruits were weighed out in front of the customer and wrapped in paper or put into a bag. In major cities in the 1880s, the milkman came around with a dipper and can to deliver milk, which was often dirty.

#### Origin of Modern Packaging and Canning

Early methods of sealing jars included waxed paper, leather, or skin, followed by cork stoppers and wax sealers. The beginning of modern food technology started with the experiments of the French confectioner Nicolas Appert (1750-1841). In 1795, the French government offered a prize of 12,000 francs to anyone who could find a way to preserve food because Napoléon Bonaparte needed to provide the military with a safe food supply. (The requirements of providing adequate food supplies for armies and navies have been of great significance in the history of modern packaging and food preservation.) After fourteen years of experimentation, Appert developed a method for preserving foods by heating. The food, meat, or vegetables, was first cooked in open kettles and placed in glass jars. After removing as much air as possible, the jars were carefully sealed with corks wired in place and then submersed in boiling water.

Appert chose glass for the container because he believed that it was air that caused the spoilage—glass is a material least penetrated by air. It is of importance to note that, in Appert's time, it was not known that microorganisms caused food to spoil. The processes in-

The introduction of the kitchen range brought about a revolution in home canning and preserving. The Mudge Stovetop Canner (shown here) was introduced in the early 1900s as a tool for sealing jars. Glass jars were placed inside the tight-fitting metal containers. Boiling water in the base caused steam, which built up pressure and thus sealed the jars. ROUGHWOOD COLLECTION. PHOTO CHEW & COMPANY.

volved in food spoilage were not understood until the second half of the nineteenth century as a result of the work of scientists such as Louis Pasteur (1822–1895) on microorganisms (Thorne, 1986).

In 1810 Appert published his prize-winning essay on food preservation and the French emperor Napoléon awarded the 12,000-franc prize to him. Within a year, an English version appeared in London, and the new method of preserving food in glass spread quickly to other countries.

### Canning

Two individuals in England are given credit for applying and improving Appert's invention, Bryan Donkin and Peter Durand. Bryan Donkin, an associate of John Hall's at his Dartford Iron Works, realized in 1811 that iron containers could be used instead of the fragile glass, and in 1812 the factory began to produce canned food such as meat. In 1810, Peter Durand patented the use of metal containers, which were easier to make and harder to break than glass jars. (The glass jars used by Appert frequently broke.) He covered iron cans, which were prone to rust, with a thin plating of tin (which is not adversely affected by water), and invented the "tin can." By 1813,

Durand was selling canned meat to the Royal Navy. The British admiralty bought these foods as part of the medical stores for distribution to sick men as well as to supply expeditions.

By 1819 canning had arrived in the United States, but no one wanted canned food until the Civil War started. In 1821, the William Underwood Company in Boston introduced commercial canning in the United States. For a long time, people regarded canned foods with suspicion, and for good reasons. In the middle of the nineteenth century, the foods produced by the canning industry were as likely to spoil as not because of inadequate heating techniques (Morris, 1958). Then, beginning in 1868, first in the United States and later in Europe, handmade cans were replaced by machine-cut types. The new technology made it possible for giant meat-canning firms like P. D. Armour to emerge in Chicago and Cincinnati. The product, however, was packed in big, thick, clumsy red cans and was not very appetizing.

The American Gail Borden was a pioneer in food canning. In 1856 he successfully produced sweetened condensed milk in cans and was granted a patent on the process. With financial support, the New York Con-

densed Milk Company was established in 1857. The demand for condensed milk was at first limited, but during the American Civil War (1861–1865) it was introduced on a large scale. The Civil War contributed significantly to the popularization of canned foods in general (Clark, 1977). The army had to be fed and the government contracted with firms to supply food. Under difficult circumstances, people learned that canned foods such as condensed milk can be tasty and nourishing. The invention of practical can openers at the end of the nineteenth century made cans easier to open, making them even more convenient for consumers.

For many years, however, the flavor of most canned food left much to be desired. On the other hand, it should be realized that products such as canned peas and salmon were usually sold to people living on the American prairies or in the urban slums in Great Britain, most of whom had never eaten the fresh product. In addition, losses due to spoilage caused by microorganisms remained high. It was not until the end of the nineteenth century that research carried out at Massachusetts Institute of Technology made a substantial contribution to improving the keeping quality, nutritional value, and taste of food products preserved in cans and glass.

In the early twentieth century, the heavy cans were replaced by those made of lighter materials, and manufacturers could stress that their products were hygienically processed and, therefore, safer to eat than the traditionally unpackaged products that had been sold in bulk. As food technology advanced, numerous chemical additives were developed to control or speed up food processing and to increase the keeping quality of canned foods.

Originally, the nutritional value of food preserved by canning was not high, mainly due to the length of time required by the heating techniques. From the 1920s onward, however, the nutritional value of canned foods gradually approached that of the fresh product, thanks to modern food technology. Finally, in the 1960s, Reynolds and Alcoa companies succeeded in making all-aluminium cans out of one piece of metal, thereby solving the problem of the weight of the cans; only the lid needed to be attached (Clark, 1977). At the same time, the invention of the rip-off closure and the pop-top lid on aluminium cans made them even more convenient, and made can openers unnecessary. For consumers, the choice between fresh or canned food became largely a question of taste, convenience, and preference.

### **Glass**

Despite its fragility and high production costs, glass had an advantage over cans: glass is chemically inert. In a metal can, iron, tin, and even lead may interact with the water of the preserved food due to chemical or galvanic reactions (although that problem had been solved when iron was replaced by lighter material). The problem of lead contamination had been removed in 1904 when the

production system of the Sanitary Can Company in New York made soldering of the can unnecessary. Glass became a relatively cheap and convenient form of packaging in 1903 when Michael J. Owen in Britain invented a semiautomatic machine for producing both jars and bottles. In the nineteenth century a major problem with glass containers had been finding a way to close a relatively expensive container without making the bottle or jar useless after it had been opened (Lief, 1965). Glass bottles could be closed with a cork, but closing bottles and jars that had wide mouths remained a problem.

Numerous ingenious inventions and innovations sought convenient ways to open and close glass containers (and cans as well). The breakthrough came with the invention of the zinc cap for the shoulder-seal jar. The most significant inventions were the Mason Jar in 1858 (named for its inventor, John Landis Mason), a glass jar with a thread at the neck that could be closed by screwing on a metal cap, and the Crown Cap for bottles, invented by William Painter in 1898.

In rural households in Europe from the 1890s until about the 1950s, food preservation in jars of glass and bottles by means of Appert techniques was common (Shephard, 2000), and small portable canning machines made it possible to use the new food preservation techniques in the 1930s and 1940s. As the technology of food preservation improved, however, homemade food preservation by means of salting and pickling in pots and jars of glass gradually decreased. With the invention of the home freezer, it largely disappeared.

### **Food Wrapping, Paper, Cartons, and Plastic**

Paper and cardboard cartons emerged at the end of the nineteenth century as material for wrapping and packaging food. For a long time the price of materials for food packaging—tinplate, glass, and, to a lesser extent, paper—remained high and was often more costly than the food itself. Technological innovations made it possible to produce packaging material cheaply. Paper became important for wrapping food when it could be produced from wood pulp, but paper and cardboard cartons were not yet suitable for packaging fluids. In the 1880s in the United States, paper and cartons could be made impermeable to fat and fluid by coating them with a thin film of paraffin.

In the 1930s, cellophane became an important material for food packaging, but it was gradually replaced by the expanding possibilities of polyethylene and other forms of plastic (Borgstrom, 1967). Another breakthrough was the invention of the Tetra Pak in Sweden in 1952, which increased the capabilities of carton containers for packaging milk, fruit drinks, and other liquids. The carton container coated with polyethylene became a serious threat to the market for glass and cans.

In the 1940s, food packaging entered the era of fully disposable packaging. The convenience of the microwave was further enhanced in the 1980s with the de-

velopment of special packaging materials. The demand for ready-to-eat fresh vegetables and fruits stimulated the development of Modified Atmosphere Packaging (MAP).

### Labels and Brand Names

Closely associated with the history of food packaging is the development of food labels and brands (Opie, 1987). In the first half of the nineteenth century, food manufacturers realized that their products would sell better if a brand name was attached to them, a name with prestige that potential customers could easily recognize. Initially, labels with information about the contents were put on glass containers or cans. Gradually, the label and the packaging as a whole became a means for promoting the food product. In most industrialized countries, legislation regulates the information that must be provided on packaging for consumers' protection.

Since the beginning of the nineteenth century, food packaging has been closely associated with industrialization and urbanization. Originally, food packaging in glass and cans was primarily meant to preserve food, but convenience became the most significant aspect of food packaging in the twentieth century. The retail revolution, when supermarket chains supplanted family-owned grocery stores, made food packaging an indispensable part of urban food culture. On the other hand, it created problems of waste disposal, a much-discussed concern of critical consumers.

### PACKAGING AND CANNING, MODERN.

Food packaging is an important part of food processing operations and food preservation. "Packaging" ensures

safe product delivery to the ultimate consumer in a sound condition and at a minimum cost (Paine and Paine, 1983). In the last quarter of the twentieth century, many important developments in both materials and packaging systems led to the reduction of packaging costs and the development of novel and minimally processed foods.

Packaging serves a number of different functions including preservation, containment, and convenience. Preservation is one of its major roles: packaging protects the contents against environmental, physical, and mechanical hazards (oxygen, water/moisture, light, contamination from microorganisms, rodents, and insects, physical damage, chemical attack, etc.) during storage and distribution. Containment is another important function: packaging contains the food and keeps it secure until it is used. Packaging is also a means of providing useful information to the consumer; communication is its third important function. It provides a way of identifying the contents; attractive or eye-catching packaging helps to sell the product; and it provides a means of fulfilling any regulatory requirements concerning labeling of foods. In addition, food packages provide convenience: they unitize or group products together in useful amounts, have features like easy opening, dispensing, resealing after use, and so on. Finally, a successful, effective food package should fulfill many other requirements. It should have good machinability (that is, it should be easily filled, closed, and processed at high speeds); it should be aesthetically pleasing, recyclable or reusable, nontoxic, tamper-resistant (or tamper-evident); it should have a functional size and shape, be disposed of easily, have low cost, and be compatible with the food it contains.

There are three levels of packaging: primary, secondary, and tertiary. A primary package is in direct contact with the product. Usually, primary packages provide the major protective barrier. A secondary package usually contains several primary packages, and provides the strength for stacking in the warehouse. Like the secondary, a tertiary package contains a number of secondary packages. Its function is to hold together the secondary packages during distribution.

Due to the large variety of food products, a great deal of packaging materials, container types, packaging systems, and techniques exist. The selection and development of a package depend on the nature of the food, the desired shelf life of the product, the storage conditions, and the cost. It is a difficult task and requires in-depth knowledge of the food product and its deterioration mechanisms, transportation hazards, market and distribution requirements, and, finally, the properties and characteristics of all available packaging materials, machines, and systems.

### Paperboard

Paper, and some combinations of paper-based packaging material, represents the most economical form of packaging. About 50 percent of all paperboard packaging is

used to form corrugated boxes, and another 25 percent goes into fiberboard cartons. Paperboard packaging provides absolutely no oxygen or moisture protection for the product, but it does provide rigidity, mechanical support, and light barrier properties. Fiberboard cartons are popular forms of packaging materials: they are economical, collapsible, and printable; they provide versatility and excellent mechanical handling; they can have dispensing and/or resealing features, windows for product observation, and they can be used in multipacks. Another type of paperboard packaging, the corrugated box, is the most common type of shipping container. Paperboard is also used for the manufacture of composite cans and aseptic cartons, which consist of combinations of thin layers of aluminum foil, paperboard, plastic, adhesive, and coatings. The layers are either wound around a mandrel (composite can) or layered in a sheet (aseptic carton).

### Glass

Glass containers are generally classified into two groups: bottles with narrow necks and jars with wide necks. Glass is chemically inert, it provides nearly absolute protection from oxygen, moisture, microorganisms, rodents, and insects, and, if colored properly, can filter out harmful UV light. However, glass has two negative properties: its heavy weight and fragility. Consumers prefer plastic packages to glass containers because plastic is lightweight, convenient, and not fragile. As a result, plastic packaging has replaced glass containers for many products and continues to do so. For example, glass containers for packaging milk, fruit juices, cooking oils, mayonnaise, soda drinks, and salad dressings have been replaced by plastic ones. Recently, the development of high-temperature resistant plastics led to the partial replacement of glass containers for jelly, ketchup, and spaghetti sauces. As plastic technology advances, other products usually packaged in glass containers will also be packed in plastic.

### Metal

Metal containers, specifically those called “tin cans,” have been widely used in the past and are still used for the production of commercially sterilized food products. The development of the metal can and the sterilization process are closely related. The series of operations that are part of the sterilization process is commonly called “canning.” In canning sterilization processes, the product is sealed in a metal container and then treated thermally in order to destroy all pathogenic and spoilage microorganisms. This sequence of operations does not allow recontamination of the product after thermal treatment, and, as a result, it remains shelf-stable for a long period of time.

The use of metal containers has many advantages: they can be sealed hermetically; they provide excellent protection from gases, moisture, microorganisms, rodents, and insects; they are stackable, tamper-proof, and relatively inexpensive; and, in general, they can be thermally processed. On the other hand, the quality of the

final product in cans is generally low; there are some safety issues (cut fingers); the containers are heavy, easily damaged, and not microwavable; and they usually do not open easily.

The most common type of metal container is the three-piece can, which consists of two ends and one body. One of the ends is applied by the can manufacturer and the other by the food packer. Most steel-based, three-piece can bodies are welded together, but they can also be secured mechanically. Aluminum cans cannot be welded economically. As a result, most aluminum cans are two-piece containers. Most metal containers are thermally processed. A series of ridges, known as “cluster beads,” are embossed in the sidewall of the can to improve its strength and prevent collapse or paneling when pressure differential is encountered during the thermal process.

Two-piece metal containers consist of a can body and one end applied by the food packer. Two-piece cans are rapidly replacing three-piece cans due to their aesthetic appeal and their lower cost.

The portion of the can formed by rolling the curled edge of the end and the can body together, forming a hermetic seal, is called a “double seam.” The double seam is a critical part of any can because it is the weakest point of the can. Each component of the double seam (Figure 1), particularly the overlap, must have the correct dimension and conform to strict guidelines to ensure a tight seal. A thermoplastic sealing compound attached to the cover melts during the formation of the double seam, fills the spaces in the seam, and results in a hermetic seal.

Most metal containers use the “tinplate” as their basic construction material. The tinplate is composed of a thick layer of steel with tin added on either side. The tin layers protect the steel from being corroded by the prod-

FIGURE 1

TABLE 1

**Plastic materials used for food packaging and some of their properties**

Properties – characteristics	Materials					
	PE	PP	PET	PS	PVC	Composite materials
Barrier:						
Moisture	Excellent	Excellent	Good	Poor	Medium	Excellent
Oxygen	Poor	Poor	Good	Poor	Poor	Excellent
Thermal stability and sealing	Excellent sealant; non-retortable	Retortable; good sealant	Hot Fill up to 185°F; crystallized form retortable (CPET)	Heat barrier (styrofoam)	Good sealing strength; microwaveable	Easy to seal or double seam
Mechanical	Good puncture resistance; can be made stiff	Good for films, stiff, brittle at low temperatures	Excellent resistance to mechanical abuse	Brittle form (HIPS)	Stiff and rigid when unplasticized	Not convection ovenable; retortable; need to protect from moisture
Chemical	Flavor scalping	Blooms; oil and grease resistant		Oil and grease resistant		
Optical	Cloudy appearance w/o colorant	Cloudy	High clarity	Good clarity	Good clarity	
Cost	Very low	Low	Moderate	Low	Low	High
Recyclability	Recyclable	Recyclable	Easy to recycle	Recyclable	Recyclable	Not recyclable

uct and by atmospheric moisture. Beyond the tin layers, there are coatings that also help to protect the metal from corrosion.

Decreasing tin resources and the resulting increase in the price of tin led to the development of tin-free steel (TFS). Tin-free steel plates use phosphates, chromium, aluminum, or nickel as protective coatings.

Aluminum cans are also coated for protection against corrosion. They are mostly used for carbonated beverages (beer and soda) because the high internal pressure helps the thin, soft metal container hold its shape and withstand mechanical damage.

### Plastics

Plastics are long-chain polymers that can be melted, formed into a desired shape, and solidified during cooling. The general advantages of using plastic materials in food packaging include consumer acceptance and preference, excellent safety characteristics (nonfragility), less weight than other materials, good moisture and gas barrier properties, good puncture resistance, low heat conductivity, good sealant properties, recyclability, and microwavability. On the other hand, potential disadvantages include flavor scalping and migration issues. (“Flavor scalping” refers to absorption of the product’s flavor compounds by the packaging material, and, conversely, “migration” is the transfer of compounds from the package to the product.)

There are many different plastics available for food packaging. The most important plastics in terms of volume are: (1) low density polyethylene (LDPE); (2) high

density polyethylene (HDPE); (3) polypropylene (PP); (4) polyethylene terephthalate (PET); (5) polystyrene (PS); (6) polyvinyl chloride (PVC); and (7) composite multilayer structures. The properties of the different plastics are presented in Table 1.

In addition to these plastics, other types are also used as food packaging materials, but they are not as popular due to their high cost. As a result, they are used only when their properties are required for the package. These plastics include: polyvinylidene chloride (PVDC), an excellent gas and water vapor barrier material; ethylene vinyl alcohol (EVOH), with excellent gas barrier properties; and some acrylics and nylons.

### Laminates

When two or more plastic films are combined together, either with an adhesive or by co-extrusion, they form a laminate. The purpose of laminating materials is to combine the best properties of each film into a single packaging structure. The combination of different films into a laminate can provide a stronger seal, better mechanical properties, machinability, barrier properties for moisture, gas, odor, and light, graphics quality, and, in general, improved characteristics and appearance at a relatively low cost. Some disadvantages of the laminates include their low line speeds and environmental issues, since they are not recyclable.

When very low gas and moisture transmission through the package is desired, the use of an aluminum foil-laminated film is required. However, sometimes, when the foil in the laminate is very thin, it becomes sus-

ceptible to flex-cracking and pin-holing, which reduce significantly its barrier properties. A solution to this problem is the use of the metallization process. Vacuum metallization is the deposition of a thin metal layer on a polymeric material under vacuum. Metallized films are not as susceptible to flex-cracking or pin-holing, which gives them a distinct advantage over foil-laminated films. The most common metallized film is oriented polypropylene, which is used widely by the snacks industry, particularly for pretzels and potato chips.

Plastics and their laminations are used to make a variety of packages: bottles, cups, trays, tubs, pouches, bags, films/flexible packages, and composite structures. The large variety of plastics with a wide range of properties, and technological innovations in plastic manufacture, are the main reasons that plastics and their laminations are used increasingly for food packaging. At the same time, these technological innovations have led to the development of many novel and minimally processed products.

### **Microwavable Packaging**

A major area of packaging development is in the microwavable products category. Consumer demands for convenient foods that need minimum time for preparation are satisfied by the use of plastics and their combination with other packaging materials that allow the product to be rapidly heated in a microwave oven. As a result, many shelf-stable, refrigerated, and frozen microwavable products are available in markets.

Another popular application in this category is the metallization of plastics and the development of susceptor technology for microwavable products (susceptors are metallized portions in packages that reflect microwaves). In the microwave, the metallized area creates localized hot spots to enhance heating, and, in some cases, to assist with browning. Examples of susceptor packaging include microwave popcorn, frozen dinners, and frozen pizza.

### **Modified Atmosphere Packaging**

Another recent packaging development involving plastic films is modified atmosphere packaging (MAP). This method involves the alteration of the composition of the air in the package. This can be done by mechanically removing the air and obtaining vacuum, by flushing the package with another gas or mixture of gases, or naturally by the respiring product in the package (Floros, 1990). The modification of the atmosphere has a desired effect on the quality and shelf life of the product. Thus, modified atmosphere packaging can be considered an integral part of the processing operation. The composition of the modified atmosphere depends on the nature of the product and the desired outcome. The barrier properties of plastics play an important role in obtaining the desired result. The gases used for atmosphere modification include oxygen, carbon dioxide, nitrogen, carbon monoxide, sulfur dioxide, ethanol, and argon. The purpose for

using each gas varies. Research regarding the use of ozone, chlorine dioxide, and other gases with antimicrobial properties indicates that the use of such gases in modified-atmosphere packaging increases the safety of the products.

The market for fresh-cut and minimally processed produce has grown tremendously over the past ten to fifteen years, and this is the result of the development and availability of plastic materials, packaging systems, and technologies, such as modified atmosphere packaging, that extend the shelf life of these products. Active packaging is a special type of modified atmosphere packaging. It involves the addition of an active substance inside the package that will cause a certain modification during storage. The substances used may be oxygen absorbents, moisture absorbents/regulators, antimicrobial agents, or other compounds with specific properties. An evolving technology is the incorporation of active substances into the packaging material itself (Floros, Dock, and Han, 1997).

### **Aseptic Packaging**

One of the major applications of laminates is in aseptic packaging. The major difference between aseptic packaging and traditional methods of food packaging is that the product and the packaging material are continuously sterilized separately. Then, under aseptic conditions that prevent recontamination of the product, the sterile package is filled with the sterile and cooled product and hermetically sealed to produce a shelf-stable final product with extended shelf life and no need for refrigerated storage. This technique has allowed for substantial improvements in the quality of the final product, mainly due to the much milder heat treatment that the product undergoes compared to the traditional thermal process (Floros, 1993).

A popular aseptic package is the "brick pak," a type of aseptic carton. Its composite structure usually contains both paper and aluminum foil. Paper is a mechanically stable, stiff, and groovable material with good heat resistance. It also provides good light protection and a printable surface. On the other hand, aluminum foil is an excellent gas, water, and light barrier (particularly when laminated between two plastic layers) and it is thermally stable. The combination of these properties has made paper/foil/plastic laminations popular in aseptic packaging. Aseptic cartons are used extensively for products such as fruit juices, milk, and other drinks.

Many changes in the packaging of food took place in the last quarter of the twentieth century, producing a wide variety of materials and technologies. The steady accumulation of research developments indicates that food packaging will continue to evolve and respond to the increased needs and demands of consumers.

**PALEONUTRITION, METHODS OF.** There are several kinds of data that inform us about what our ancestors ate. Reviewed in this entry are the data from studies of living primates, archaeology, paleontology, and living hunter-gatherer societies.

### Primate Studies

The living primates include prosimians, New World monkeys, Old World monkeys, Asian and African apes, and people. Fossil evidence indicates that all primates evolved from insectivore-like mammals that lived some seventy-five million years ago. Primate ancestors may have been those insectivores that moved into the flowering trees of these tropical forests to exploit insects, and then the flowers, fruits, gums, and nectars of those trees. The large number of essential nutrients required in the human diet (forty to fifty essential nutrients) is likely a consequence of the tropical primate diet. Tropical forests are characterized by having a high diversity of species, but a low density of any given species. With a wide va-

riety of food resources, especially fruit, foliage, and insects, ancestral primates were able to obtain many vitamins, minerals, protein, carbohydrates, and fats from their diet. It is metabolically expensive, in terms of energy consumption, for an organism to manufacture its own nutrients (a process called autotrophism). Through mutation and selection, those early primates that reduced autotrophism, and shifted to a dependency on dietary intake to meet their nutrient needs would have gained an energetic advantage, one that could be put to use, for instance, to increase reproduction.

The human primate is unusual in that seeds, grasses, roots, and vertebrate meat are major components of both its modern and ancient diet. Grasses and roots are the category of plant food most often missing from the diet of other primates. Seeds, grasses, and roots have their nutrients protected by cellulose membranes that must be mechanically broken. This can be done by mastication (chewing), or by using technology. Humans, and our hominid ancestors dating back to *Australopithecus*, possess the anatomy (e.g., small canines, flattened molars, and enlarged pterygoid muscles—those that move the lower jaw from side to side) that allows for a type of chewing called rotary grinding, which can break cellulose. Humans, and our ancestors of the genus *Homo*, are also dependent on technology (e.g., tools or fire) for food processing. Technology is also required for hunting at a level that makes vertebrate meat a regular part of the diet. For this reason, meat from vertebrates, either hunted or scavenged is not reported as a major component for any nonhuman primate species, although some baboons and chimpanzees regularly hunt mammalian prey.

### Archaeology and Paleontology

Archaeological methods focus on the recovery and identification of food remains, of tools and other artifacts used for the acquisition and processing of food, on the analysis of food contained within coprolites (fossilized feces), on the reconstruction of ancient habitats, and on the analysis of hominid fossils. Paleontological data are derived from the kinds and percentages of fossil remains found at a site. Each type of evidence contributes some knowledge, but each has serious limitations. The association of hominid fossil remains with the skeletal remains of other fossil vertebrates may result from geologic forces, such as rivers carrying dead carcasses to a central location or a volcanic eruption burying simultaneously a community of animals, rather than hominid food gathering behavior.

In *The Descent of Man* (1871), Charles Darwin proposed that hunting large game provided much of the selection pressure for human evolution. That view persisted through the 1960s, but more recent data, based on fossil and archaeological remains and the study of living hunting and gathering people, such as the !Kung and Australian Aborigines, show that gathering and processing of plant foods is the main activity of tropical foragers.

Moreover, women in living foraging societies provide most of the calories consumed by these people. These observations turned “man the hunter” into “woman the gatherer.”

Additional evidence is based on analyses of bone and stone tool material associated with early hominids. Scanning electron microscope images of mammalian long bones dating to 1.7 million years ago show that cut marks produced by stone tools were incised above those made by carnivore teeth and the teeth of known scavengers, such as porcupines. If one assumes that the order of markings reflects the order of use by hunters and scavengers, the hominids were the last to have at the bones, even after porcupines. Early hominids may have been collecting bones for their marrow and brain tissue rather than for any meat still remaining on the surface of the bone. Marrow and brain are high in fat and protein, but few carnivores have the morphology necessary to break open large long bones. The invention of stone tools, first manufactured by hominids about 2.2 million years ago, may have been a dietary adaptation for extracting marrow. Hominids may also have scavenged for larger pieces of meat, perhaps stealing meat from leopards. Leopards carry their kills up into trees and consume their prey over several days. J. A. Cavallo believes that human ancestors may have scavenged these arboreal caches of meat.

Despite the evidence for scavenging animal carcasses and, perhaps, preying on leopards, the bulk of the hominid diet has almost always been from plants. The stone tools of the early hominids may also have been used to process hard to chew plant foods, such as seeds. Studies of the finer details of early hominid dental structure and tooth wear using the scanning electron microscope and tooth wear experiments found that the diet of the early hominids, including *Australopithecus* and *Homo habilis*, was largely herbivorous, including softer plant foods (leaves, fruits) as well as the tougher seeds and tubers. Given all the evidence now available, perhaps it is safest to say that the gathering of plants, insects, bird's eggs, and other relatively immobile foods and the scavenging of marrow from carnivore kills typified early hominid food behavior.

*Homo erectus* added fire to its repertoire of technology. Fire, which may have been used as early as 1.4 million years ago and was certainly controlled by 750,000 years B.P., provided warmth, light, protection, and a new way to process foods. Where and how cooking was invented is a matter for speculation. Cooking, by roasting or boiling, increases the nutritional benefit of many vegetable foods by helping to break down the cellulose of those foods that is indigestible to people. Fire may be used to open large seeds that resist even stone tools. Cooking, especially drying or smoking, helps to preserve foods for storage. Fire may also be used to get foods, especially by driving game towards a convenient killing site. All of these uses of fire did not appear simultaneously, and many appear to be the invention of *Homo sapiens* rather than *Homo*

*erectus*. What is certain is that the controlled use of fire was a significant addition to hominid technology with profound consequences for nutritional status.

Coprolites are fossilized feces. Such “hard evidence” might seem to provide unequivocal verification of dietary habits, but coprolites are subject to misinterpretation. First, the coprolite must be identified unambiguously as being from a hominid. Second, coprolites can only verify that a particular substance was eaten. That substance may or may not have been a food item itself, it may have been ingested coincidentally along with a food, such as a seed or insect clinging to an animal or plant. Third, only indigestible substances will be found in feces and those substances must be suitable candidates for fossilization to be preserved in a coprolite. Thus, coprolite analysis may provide a very biased picture of the true dietary intake. Even so, considerable information has been obtained about the diet of prehistoric humans and limited information about the diet of hominid species ancestral to modern people. The animal affinity of desiccated coprolites can be determined by placing the specimen in a trisodium phosphate solution for seventy-two hours. Human coprolites turn the solution an opaque dark brown or black color and no other species produces this effect. Other characteristics of human feces are inclusions of charcoal and the presence of undigested animal parts from a wide variety of species. Charcoal comes from cooking food over a wood fire. Since people cook their food and other animals do not, the presence of charcoal in feces is indirect evidence for a unique human behavior. People also have an eclectic diet compared with most other mammals, so undigested parts from a wide variety of species is another indicator of the human affinities of a coprolite.

More than a thousand paleoindian coprolites from the American Southwest have been identified and analyzed. One group of specimens was collected from Texas sites that date from 800 B.C.E. to 500 C.E., representing the temporary camps of hunting and gathering peoples. By comparing the pollen content of the coprolites with that found in the adjacent soils it was determined that the people had consumed high quantities of flowers. Because the physical characteristics of flower pollens are unique to each species it was possible to determine that flowers of agave, sotol, yucca, prickly pear cactus, gilia, and lead-tree were popular foods. Also found were remains of wild onion bulbs, bark, grasshoppers, fish, small reptiles, and snails. Although not the current cuisine of Texas, this diet is typically human in its diversity of species. The flower pollen even provides a time frame for the occupation of the sites, spring and early summer.

The oldest verified coprolites of a hominid species are from the *Homo erectus* site of Terra Amata located on the French Mediterranean. These coprolites may be as old as 300,000 B.P. and they are heavily mineralized. They have only a slight reaction to trisodium phosphate rehydration. The specimens contain sand grains, charcoal, and

mollusk shell fragments. The sand and shell are expected since Terra Amata is a beach front site, and the charcoal helps establish that foods were cooked before consumption (perhaps evidence for a prehistoric clam bake).

**Trace element and stable isotope analysis.** A general picture of the relative amounts of plant and animal food in the diet may be available from chemical analyses of stable isotopes and trace elements in skeletal remains. For example, the more  $\delta^{13}\text{C}$  (a form of the element carbon) in a skeleton the more C4 plants in the diet. C4 plants include the domesticated grains maize, millet, and sugarcane, while C3 plants include virtually all those growing wild in temperate regions. The amount of the stable nitrogen isotope  $\delta^{15}\text{N}$  in skeletons indicates an animal's place within the food web. The amount of  $\delta^{15}\text{N}$  is higher as more animal protein is included in the diet. Figure 1 illustrates the relationship of these stable isotopes to diet in several mammalian species. This method is most useful when analyzing human skeletons during the transition to agriculture, that is, during the past ten thousand years. A greater dependence on agricultural crops shows up in human skeletons as more C4 plants ( $\delta^{13}\text{C}$ ) and, generally, less animal protein ( $\delta^{15}\text{N}$ ). Agricultural societies are often stratified socially into higher and lower social classes. Higher classes often have greater access to animal protein. Thus, within agricultural societies the upper classes may have more  $\delta^{15}\text{N}$  in their skeletons. This allows archeologists to use stable isotopes as markers of social status.

There are exceptions to the usual  $\delta^{15}\text{N}$  indicator of social status. In 1995 Douglas Ubelaker and coworkers analyzed the skeletons from high and low status graves at the archeological site called La Florida in Ecuador. The site dates from 100 to 450 C.E. There were no differences in the levels of protein ( $\delta^{15}\text{N}$ ) in these skeletons, but there is a statistically significant difference in the C4 levels between the two groups. The high status group had higher levels of C4. The only C4 plant—the only domesticated plant—that ancient people of highland Ecuador consumed in quantity, was maize. The researchers explain that the extra maize consumed by the elites was in the form of an expensive and politically restricted food called beer. Elites controlled the production and consumption of beer. Maize beer was produced by the chief's household and was doled out to the commoners at feasts in return for their labor. Chiefs also paid tribute to each other in the form of beer and offered copious amounts of beer at royal funerals. Chiefs were buried with many ceramic vessels, and at La Florida 70.5 percent of these were devoted to the brewing and serving of maize beer.

### Studies of Living Hunters and Gatherers

All but one-tenth of 1 percent of humans derive their food from some form of agriculture. However, from the time of the *Australopithecus* until about ten thousand years ago, a period that covers 99 percent of human evo-

lution, all hominids lived in bands and produced food by foraging—the gathering, scavenging, and hunting of wild foods. Most human physical traits, and many behavioral propensities, evolved during the time that hominids lived as hunters and gatherers. This includes current human dietary requirements, adaptations for food acquisition and processing, and biocultural responses to food. Studies of the few remaining cultures of hunting and gathering peoples offer an indirect view of that ancient style of life, now nearly extinct.

Foragers are a diverse group geographically and culturally, ranging from the arctic Inuit and Eskimo, to the tropical forest Ache (Paraguay), to the dry scrub San (Africa), and the desert Australian Aborigines. Yet, the research shows some consistencies in behavior and diet. The diversity of food resources utilized is high among gathering and hunting peoples compared with agriculturists. The !Kung San of southern Africa, for instance, eat 105 species of plants and 144 species of animals (Lee, 1984). The Australian North Queensland Aborigines exploit 240 species of plants and 120 species of animals. The Ache forage on fewer species, about 90 types of plants and animals. Even the Dogrib, residing in the subarctic of Canada, gather 10 species of plants and 33 species of animals (Hayden, 1981). That is a small food base for hunters and gatherers, but still a large number relative to agriculturalists who, on a world-wide basis, subsist largely on four species of plants (wheat, rice, potatoes, and maize) and two species of animals (cattle and hogs).

A second common feature is that gathered foods (plants, insects, bird's eggs, turtles, etc.) are the primary subsistence base in most foraging societies. Lee compared fifty-eight forager groups and found that the primary subsistence source was gathering for twenty-nine, fishing for eighteen, and hunting for eleven. Often, the use of many species for subsistence is correlated with the high diversity, low density, or seasonality of food items in the environment. In habitats where low density is combined with the wide dispersal of foods, foragers must be mobile and live in small groups. A small mobile social group is a third typical feature of forager societies. Average group size ranges from nine to fifty-five and average densities range from one to two hundred people per hundred square miles. Mobility ranges from daily movement from camp to camp to seasonal sedentariness at one camp, such as a winter lodge or a summer camp.

A fourth common feature is that all foragers depend on technology to procure, process, and store food. Technology ranges from simple to complex, both in amount and sophistication. Savanna and desert foragers, such as !Kung and Australian Aborigines, use a digging stick to get at roots and tubers that are hidden from view or not possible to extract using hands alone. The digging stick seems simple, but that tool more than doubles the calories available to the people who use it as compared with nonhuman primates living in similar habitats. Bow and

arrow are used by some groups to hunt large game. At the other extreme of material culture are the Inuit and Eskimo, who possess dozens of pieces of equipment for hunting or fishing, including hooks, spears, sleds, knives, and specialized clothing. The relative complexity of Inuit and Eskimo material culture is required to extract food from a harsh environment.

Food preparation techniques include cooking (such as boiling, steaming, roasting, and frying), soaking, grinding and grating, pounding, drying, fermenting, and putrefying (as in "aged" meat). Many human foods are poisonous prior to preparation by one or more of these techniques. Such toxic raw foods include acorns and horse chestnuts, eaten by many North American Indian foragers and manioc, a root crop, which is a dietary staple of many African societies. The toxins in all these foods are removed by leaching, that is, by boiling them in water and then allowing the food to dry prior to consumption. Rhubarb and cashews, eaten by some people in modern industrial societies, are also toxic until cooked by boiling or roasting. Finally, food storage by drying, caching, and, where possible, freezing or salting is common to many forager groups. It is essential to point out here that dependence on technology for food procurement, the processing of food, and food storage are all behaviors unique to the human species and found universally in all known human cultures.

Sharing and the division of labor comprise a fifth characteristic of foragers. All known living hunters and gatherers share some food, even small game and vegetables in many cultures, and have some division of labor indicating that this is a universal human nutritional adaptation. Sharing and division of labor may best be viewed as behaviors that, first, reduce the effects of unpredictability and variance in food supply, and, second, increase reproductive fitness—that is to say, they increase the healthy development of the individual and his or her likelihood to reproduce. By dividing the social band into working groups based on sex and age, more of the necessary subsistence tasks may be accomplished in a shorter period of time. In tropical and temperate regions, adults may gather plant foods, honey, insects and other small animal foods, and hunt larger animal prey. Children may remain at the camp in an age-graded play group, with older children caring for younger children, or may accompany their parents so as to learn foraging techniques. In extreme environments children may provide significant amounts of foraged food, as they do in Hadza society.

### Summary

The human diet is unusual because of our high intakes of grasses, seeds, and grains and, for some people, high intakes of meat. No other primate has this mixture of foods in its diet. The interaction between the biological history and the sociocultural behavior of people accounts for our diet. The human place in nature as primates explains our broad requirements of essential nutrients. Fos-

sil and archaeological evidence help to account for the development of the types of foods eaten and the technology needed for food acquisition, preparation, and storage. The study of living hunting and gathering peoples compliments and supports these other sources of evidence. Five features of food, behavior, and demography are typically found in hunting and gathering societies: a high diversity of food types; greater dependence on gathering rather than hunting; small mobile social groups; dependence on technology for acquiring and processing foods; and division of labor and sharing (a sixth feature, stable population size with high infant and childhood mortality balancing fertility, is not discussed here, but see Bogin, 2001). Taken together, the sources of knowledge reviewed here provide the basis for understanding human paleonutrition and the biocultural nature of contemporary human nutrition.

**PANTRY AND LARDER.** In modern parlance, pantry and larder are used interchangeably to designate a place where food is stored. Historically, the two were

once separate areas with very narrowly defined functions. During the Middle Ages, food was purchased in bulk; therefore, storage rooms were required for different types of food.

The larder was originally a cool room or cellar for storing meats, especially meats put down in large barrels or corks of lard—hence the name. It was once common practice to partially cook meats and sausages, and then cover them with rendered lard until needed. Dried or smoked meats were generally stored in a loft or garret away from dampness. This division of function led to the evolution of the terms wet larder (cool room or cellar) and dry larder. The wet larder was used not only for meats stored in lard, but also as a holding room for uncooked meat, game, and vegetables. The dry larder would contain such things as dried fruit, grain chests, and even some types of hard-rind cheeses. Large loaves of rye bread were often buried in the grain chests for long-term keeping.

The term “pantry,” and related words like “pantryman” and *pannier*, derive ultimately from Latin *panis* (bread). The core idea was a closet or cupboard where bread was stored, as in Old French *paneterie*, the term that passed into medieval English as *panetrie*. In aristocratic medieval households, the pantry was a standing cupboard where the bread was kept for the table. The finer sorts of cupboards were often elaborately carved since they stood in the room where dining took place.

The pantler was the servant in charge of the bread and was the individual who actually sliced it for the table. This position attracted a degree of prestige since bread was such a critical part of the medieval meal. For this reason, in households belonging to the high nobility, the pantler was often a member of the lesser nobility. By the eighteenth century this function was more or less subsumed in hotels and large commercial establishments by the pantryman, a paid position whose main function was to oversee the supplying and resupplying of bread and provisions.

During the Middle Ages, two sorts of bread came from the pantry. The best bread was the *manchet* or dinner roll (normally round) made of the finest wheat flour. This bread was held in the hand and used like a utensil for dipping or scooping, since medieval diners ate with their fingers. The other sort of bread was the trencher bread, a coarse bread usually made from a combination of wheat and rye flours. Trencher bread was sliced and trimmed of crust to make a disposable plate on which the diner placed food, since dishes were only used as serving pieces during this period. Trenchers were changed frequently during a meal because they became soggy; thus it was the pantler’s duty to remain vigilant and keep the table well supplied with trenchers.

By the seventeenth century, the function of the pantry had been expanded to include not only a bread storage cupboard, but also a closet or small room in which

The interior of a larder as depicted in a 1668 illustration by Wenceslaus Hollar for an edition of *Aesop's Fables*. Note the storage of pies and roasts for reserving at a later time. Rats in the foreground are enjoying a meal of their own. COURTESY OF TOM JAINE, ROUGHWOOD COLLECTION.

all sorts of food could be stored together. It was a cold room in that it was unheated and often ventilated with air from outside. Normally this closet stood near the kitchen, and it was common practice to put there roasts of meat, pies, and other items of uneaten food so that they could be reserved the next day. It became the butler’s duty in large households to keep tabs on what was in the pantry, and this gave rise to the idea of a more specialized butler’s pantry in the nineteenth century. This was a small room normally situated between the kitchen and dining room where fine silver, glassware, and china were stored. Aside from extensive cupboards and shelves, it also featured a sink. It was here that the butler, or his assistant, could undertake the final preparations for many dishes, such as decanting wine, heating a chafing dish, garnishing a roast on its way to table, or preparing fruit for dessert. A subsidiary pantry called the housemaid’s pantry also evolved out of this. It was here that the head maid stored her tools. Butler’s pantries were a common feature in upper-class American households on the East Coast well into the 1940s. Today, the term “pantry” has devolved into a much less specialized concept. The refrigerator and deep freezer have replaced the old larders

L. Schumacher's handbook for the "perfect" steward and pantry cook was published in Hamburg, Germany, in 1914. It includes many recipes for salads and mixed drinks and was intended for use on passenger ships between Germany and the United States. ROUGHWOOD COLLECTION.

of the past, and the breadbox has replaced the pantry. In general, pantry and larder are now applied to any unheated storage room where food is kept, especially packaged foods, canned goods, and pickles.

**PARKINSON, JAMES WOOD.** James Wood Parkinson (1818–1895) was one of the most influential American cooks of the nineteenth century. Trained by professional chefs from England, Italy, France, and Germany, his role was one of mentor to the profession rather than that of a popular cookbook author like Eliza Leslie or Sarah Josepha Hale. The core of his culinary education, however, came from his Scottish-born mother, Eleanor Wood, and his English-born father, George Parkinson, both confectioners by trade.

In 1818, Parkinson's parents purchased the Pennsylvania Arms, a Philadelphia tavern, with the intention of going into inn keeping. However, his parents' flair for confectionery soon established the family's reputation for ice cream, and it was the Parkinson family which made Philadelphia ice cream famous throughout the nineteenth century. During a banquet for the Marquis de Lafayette in 1824, the Parkinsons introduced vanilla ice cream featuring tiny flecks of the beans, thereby establishing a perfume essence as a signature flavor for a luxury desert.

By the mid-1840s, with financial backing from General George Cadwallader, the young Parkinson had established himself as a restaurateur in a lavishly furnished Philadelphia mansion located at 180 Chestnut Street. Complete with a rose garden for outdoor dining as well as a delicatessen featuring imported foods from all over the world (including five types of French liver patés), Parkinson's Salon was generally considered not only one of the finest restaurants in America, but equal to those of Paris and Vienna.

James Parkinson was a master at marketing and something of an inventive genius when it came to recipes. In 1841, his delicatessen was the first in the country to feature Santa Claus at Christmas in order to draw children into a wonderland of French confections and imported toys. In 1850, he introduced his Champagne *frappé à la glace* which is now considered to be the original recipe on which the non-alcoholic ice cream soda was based. Parkinson's fame was firmly established in 1851 when he accepted a challenge from the Delmonico brothers to prepare a dinner that would be more outstanding than one given earlier by Delmonico's. Parkinson's "Thousand Dollar Dinner" became a legend that helped launch the era of grand banquets in nineteenth century America. The menu survives and features such novelties as early eighteenth century wines, truffled poultry braised in Champagne, and a rare Tokay from the imperial wine cellars in Vienna frozen as sorbet.

Parkinson's influence continued even after he retired from the restaurant business during the 1860s. When the

Parkinson's restaurant at 180 Chestnut Street in Philadelphia was once a private mansion. There was a separate entrance for the confectionery store (on the right). Wood engraving from *Gleason's Pictorial* (May 1853). ROUGHWOOD COLLECTION.

Grand Duke Alexis of Russia visited the United States during the winter of 1871–1872 and declared that there was no true American cuisine. James Parkinson responded with his culinary manifesto *American Dishes at the Centennial*. In a call to arms for the nation's cooks, Parkinson extolled the rich variety of American ingredients and said that it was this body of regional foods that should serve as a basis for our national cuisine. It was his hope that these ingredients would be showcased at the U.S. Centennial in 1876. Unfortunately, due to Centennial politics, Parkinson was never invited to put his vision into practice, yet even today this theme is one of the underlying forces in modern American cookery.

Parkinson's manifesto also launched his career as trade editor for the *Confectioners' Journal*, a position he held from 1874 until his death in 1895. During this period he published hundreds of articles on specific topics such as "The Raspberry: Its Peculiarities and Uses," "Gelatin," or "Colored Sugars for Decoration." His material not only contains information not readily available in cookbooks of the period, but also a wide selection of rare recipes from leading cooks and confectioners.

**PASSOVER.** Passover celebrates the Exodus of the Israelites from Egypt in the second millennium B.C.E. as narrated in the Bible (Exod. 1–15). According to the Jewish calendar, the holiday begins on the evening of the fourteenth of Nisan, which falls in late March or early April. Passover is observed for seven days in Israel and eight days elsewhere. On the first one or two evenings of the holiday, Jews are required to recite the Exodus story (Exod. 13:8) at a family feast called the seder and to eat matzo, an unleavened flat bread. They are prohibited from eating foods containing leaven (*hametz*) during the entire holiday.

#### History of Passover

The eating of a sacrificial animal, together with unleavened bread and bitter herbs, was central to Passover observance until the destruction of the Second Temple in 70 C.E. However, the paschal sacrifice and eating unleavened bread actually predate the Exodus, even in the Exodus account itself (Exod. 12:8), and are associated with two distinct holidays: Pesach, a pastoral holiday during which animals were sacrificed and eaten, probably as a propitiatory measure to protect the flocks; and Hag Ha'Matzoth, an agricultural festival associated with the beginning of the barley harvest, during which unleavened bread was eaten. The Bible distinguishes these two holidays (Lev. 23:5–6; Num. 28:16–17) and, in Exodus 12, juxtaposes them. The Samaritans still observe them as two separate events. Unleavened bread was also an ordinary bread made in haste. Sarah served it to guests (Gen. 18:6), and Lot offered it to the angels (Gen. 19:3). It is thought that eventually these two spring festivals were observed together and were later identified with the commemoration of a historical event, the Exodus, which also occurred in the spring.

According to the biblical account of the Exodus, God visited ten plagues on the Egyptians to persuade them to

release the Israelites from bondage. Before the last plague, during which the firstborn in each household would be slaughtered, God told Moses to tell the Israelites to slaughter an unblemished yearling lamb or kid and smear the blood on their two door posts and lintel so their homes would be passed over and their firstborn spared. The Israelites, as instructed, roasted and ate the animals just before leaving Egypt but were in such a hurry that their bread had no time to rise (Exod. 12:1–28). Also symbolizing the food eaten by slaves and the poor, matzo is known as the bread of affliction or poverty (Deut. 16:3).

Passover became one of three pilgrimage festivals during which Israelites traveled to Jerusalem to make offerings, including the sacrifice of animals, at the Temple. They consumed parts of the roasted animal at a family feast. After the destruction of the Second Temple, animals could no longer be sacrificed, but the practice was remembered through symbols, such as the roasted shank bone placed on the seder table.

After the destruction of the second Temple in 70 C.E. and the wide dispersal of the Jews, Passover was gradually codified, and many local variations developed. The laws concerning Passover are in the Bible (Exod. 12–15), Tractate Pesachim of the Mishnah and Toseftah (compilations of the Oral Law completed in about 200 C.E.), Talmud, and later works. The *Shulhan Arukh*, written by Joseph Caro (1488–1575), with glosses by Rabbi Moses ben Israel Isserles (1530–1572), is the basis for modern religious practice.

### Haggadah

The story of the Exodus is recounted from the Haggadah, which means ‘narrative’ in Hebrew, at the seder, during which participants eat foods symbolizing the Exodus from Egypt. The traditional Haggadah, which contains passages from the Bible and the rabbinic literature, blessings, prayers, and songs, is based on a compilation that began to be assembled in the Second Temple period. With several core elements in place by 200 C.E., the Haggadah continued to evolve, as did the seder, whose form is set out in the Haggadah.

The diverse Jewish communities of the Diaspora have created thousands of distinctive Haggadahs and modified them to reflect such concerns as egalitarianism (removing masculinist language), feminism (emphasizing the role of women in the Exodus story and in Jewish history), environmentalism (adding pollution and other dangers to the list of plagues), oppression (expressing solidarity with African Americans, Soviet Jews, Tibetans, Palestinians), social justice (adding poverty, homelessness, and AIDS to the list of plagues), humanism (stressing the theme of freedom rather than divine intervention), personal liberation (freedom from addictions), and remembering the Holocaust. These texts have encouraged the creation of new kinds of seders, whether adaptations of the seders held on the first two nights of Passover or a special third seder, as well as new and newly

interpreted symbolic foods and cuisines. For example, Tibetan food is served at interfaith and international seders for a free Tibet, whether on American university campuses or in Dharamshala, India, home of the Dali Lama in exile.

### Seder

The seder is organized around seven symbolic foods. They include three matzoth (two in some communities); four glasses of wine; a roasted bone (*zeroa*) symbolizing the Paschal animal sacrificed at the Temple; a green vegetable for spring; bitter herbs (*maror*) for the bitterness of slavery and for the ancient practice of eating hyssop with the Paschal offering; a roasted egg symbolizing a festival sacrifice once made at the Temple; and a mixture of fruit, nuts, spices, and wine or vinegar (*haroset*) for the mortar used by the enslaved Israelites.

Ashkenazim (Jews who derive from Germany and central and eastern Europe) present these foods on a special seder plate. Some Sephardim (Jews who derive from the Iberian Peninsula and the places they settled after the Expulsion in 1492) place these foods in a basket. Yemenite Jews set little bowls on a table covered with leafy green vegetables. In the late twentieth century, vegetarians replaced the bone with a roasted beet, or “Paschal yam,” to symbolize the blood of the Paschal lamb. Among the many new Passover traditions is an orange on the seder plate, a practice introduced in the early 1980s by Susannah Heschel as a gesture of solidarity with those who have been marginalized within the Jewish community, including lesbians, gay men, and widows.

The seder, which means ‘order’ in Hebrew, proceeds through a set sequence of fifteen elements. These include blessings on the wine, the matzoth, and other symbolic foods; blessings and ceremonial washing of the hands; recitation of the Haggadah; eating the festive meal; the *afikoman* (half of the second of two or three matzoth); grace before and after the meal; and concluding songs and poems.

Many customs vary. Toward the end of the seder, Ashkenazim set aside a special goblet of wine for the Prophet Elijah and open the door to allow him to enter. The arrival of the Prophet Elijah is believed to herald the coming of the Messiah. A feminist innovation is the addition of Miriam’s goblet, which is filled with water because Miriam, the older sister of Moses, is called a prophetess in the Exodus account and is associated with a miraculous well (Exod. 15:20). According to Erich Brauer (*The Jews of Kurdistan*, 1993, first published in 1947), with the mention of each of the ten plagues, Jews from Ushnu dip a finger in wine and shake a drop into an empty eggshell, to which they add some arrack, tobacco, and bitter herbs. Then “one of the men takes the egg and in silence throws it on the doorstep of one known to hate the Jews, returns in silence, and washes his face and hands before taking any further part in the Seder” (Brauer, 1993, p. 288). During the song “Dayenu,” in

which the refrain “that would have been enough” follows a verse describing how God executed justice, some Sephardi, Afghani, and Persian Jews beat each other gently with scallions to symbolize the lashes of Egyptian taskmasters.

### Haroset

*Haroset* is eaten at points nine (*maror*) and ten (*koreh*) in the seder sequence, after which the meal proper commences. Many of the ingredients in *haroset*, which vary from one community to another, have symbolic significance. The spices stand for the straw that was mixed into the mortar, red wine refers to the plague of blood, sweetness signifies hope, apples are mentioned in the Song of Songs (8:5), and various fruits (figs, dates, raisins) are associated with Bible lands. Ashkenazim favor apples, nuts, cinnamon, and red wine. Yemenite Jews, who refer to *haroset* as *dukeh*, a Talmudic term that only they use, combine dates, raisins, dried figs, roasted sesame seeds, pomegranate, almonds, walnuts, black pepper, cumin, cinnamon, ginger, cardamom, and a little wine vinegar. The Lopes family in Jamaica makes a paste of dates and sultanas soaked in orange juice and adds grated citron rind, port wine, and shredded coconut. The paste is shaped into little bricks and dusted with cinnamon (Michel, 1999).

### Afikoman

The *afikoman*, a reminder of the Paschal sacrifice, is the last morsel consumed at the seder. The word *afikoman* derives from the Greek *epikomion* (‘dessert’) and *epikomioi* (‘revelry’), which are associated with the final phases of the Greek symposium. While the seder resembles the Greek symposium in other ways, most importantly Socratic dialogue and learned discussion in the context of a festive meal (the symposium generally followed the meal), the rabbis stressed the differences between them because the symposium was associated with excessive drinking and licentious behavior. Many similarities between the seder and symposium (drinking wine, reclining, song) were characteristic of ancient banquets rather than unique to either of them, but these and other common practices (for example, dipping appetizers in a condiment) acquired special meaning in the Passover seder.

Ashkenazim hide the *afikoman* and reward a child for finding it at the end of the meal. While neither Sephardic nor Yemenite Jews hide the *afikoman*, they do reenact the Exodus, consistent with the obligation stated in the Haggadah that one is obliged to see oneself as if one had personally left Egypt. Syrian Jews do this by wrapping the *afikoman* in a special embroidered napkin cover, throwing it over their shoulders, reciting Exodus 12:34, and then asking and answering the following questions in Arabic: Where are you coming from? (Egypt) Where are you going to? (Jerusalem) (Dobrinsky, 1986, p. 256). In some Mediterranean and Central Asian Jewish communities, a piece of the *afikoman* is saved as a protection against misfortune. It is also a Sephardic custom, when breaking the

Manuscript illumination from the fifteenth century showing a couple celebrating the Passover seder. © ARCHIVO ICONOGRAFICO, S. A./CORBIS.

*afikoman* during the seder, to do so in a way that forms a letter of symbolic significance.

### Matzo

Although matzo is required only during the seder, it is customary to eat matzo throughout the holiday. To mark the distinction, many Jews use guarded (*shmurah*) matzo for the seder and regular matzo on the remaining days, while others eat *shmurah* matzo throughout the holiday. To ensure that the grain never comes into contact with any water or trace of leaven, *shmurah* matzo is guarded from the moment the wheat is harvested until the matzo leaves the oven, whereas regular matzo (*matzo peshutah*) is made from wheat that has been supervised only from the point of milling. Of concern is the practice of tempering grain by moistening it with water before milling. The flour for *shmurah* matzo is mixed with *mayim she-lanu*, water that has been drawn from a natural source after sunset and left to stand overnight in a cool place.

All matzo, to be kosher for Passover, must be made from dough mixed, kneaded, rolled, perforated, and baked at a high temperature within eighteen minutes. A rabbi supervises the process and checks that the matzoth are properly backed, with no bubbles, folds, or soft spots. Between each batch of matzoth, tables and tools are scrupulously cleaned to ensure that no traces of dough

adhere to them. In Yemen, Jews used to bake matzoth during Passover in order to have fresh soft matzoth throughout the holiday. Baked directly on the walls of a clay oven, these matzoth were somewhat like pita. Yemenites served thick matzoth at the seder, as did medieval Jewish communities, and thin ones during the rest of the holiday.

A traditional rich matzo (*matzo ashirah*) is made with white grape juice or eggs rather than with water. Only those who have difficulty digesting regular matzo, including the sick, elderly, or young children, may eat this kind of matzo during Passover. The Talmud and later sources debate the permissibility of decorating matzoth, whether by pressing them into molds or perforating them to make patterns, because the extra time devoted to this process might cause the dough to ferment. Illustrated Haggadahs show, however, that matzoth were indeed ornamented. In 1942, matzoth in the shape of V, for victory, were baked in the United States.

Rolled by hand, *shmurah* matzoth are round, in contrast with the square matzoth made by machines introduced during the 1850s in Austria. Machine-made matzoth were controversial for several reasons. First, round matzoth were stamped out of sheets of dough. Because the scraps were reused, there was a delay between mixing and baking the dough, prompting concern that the dough would start to rise. Second, to fulfill the religious obligation of eating matzo during the seder, matzo must be made intentionally for that purpose. Whether or not the intentional starting of the machine is sufficient to meet this requirement has been debated, and steps have been taken to increase human involvement in the machine process.

In time, square matzoth made by machine came to be widely accepted, so much so that matzo companies, such as Manischewitz, established in Cincinnati in 1888, made every effort to diversify their matzo products and to create a market for them all year round. Since the 1930s, their cookbooks have provided recipes for how to use their matzo products in everything from tamales to strawberry shortcake. In the late twentieth century, Manischewitz added an apple cinnamon matzo to its product line. Chocolate-covered matzo has become popular.

The claim that Jews added a victim's blood to the matzo or drank the blood at the seder is a late addition to the long history of blood libels accusing Jews of kidnapping and killing a Christian, usually a child. Blood libels have led to the execution of accused Jews and the massacre of Jewish communities. In 2002 in Saudi Arabia, a blood libel accused Jews of using the blood of non-Jewish teenagers in their Purim pastries.

### Hametz

Whereas one is only obligated to eat matzo at the seder, *hametz* is prohibited during all eight days of Passover. *Hametz* refers to any of the five species of grain men-

tioned in the Bible (wheat, rye, oats, spelt, barley) that have come into contact with water after being harvested and allowed to ferment. These grains and anything that has come into contact with them or has been made from them cannot be eaten or be in one's possession during the holiday. Preparation for Passover entails a scrupulous cleaning of the home to remove every last trace of *hametz*, the "sale" to a non-Jew of any remaining *hametz* in one's possession (and repurchase following the holiday), the use of dishes and utensils dedicated exclusively to Passover or specially prepared for that purpose, and consumption of food that is kosher for Passover.

To prevent any possibility of violating the prohibition, "fences" have been created around these rules. Many Ashkenazim do not eat *kitniyot* (legumes, grains, and beans, including lentils, rice, corn, peas, millet, buckwheat, and anything made from them or their derivatives, such as oil, sweeteners, or grain alcohol). Sephardim generally eat fresh beans, and some groups eat rice. Most Hasidim do not eat *gebrokts* (matzo, whether whole, broken, or ground into meal, that has been mixed with water). Italian Jews do not consume milk during Passover, while Ethiopian Jews abstain from consuming fermented milk products. Many Jews do not conform to these restrictions, while some observe *kashruth* (Jewish dietary laws) during Passover but not during the rest of the year.

### Cuisine

Passover dietary restrictions and requirements have prompted distinctive culinary responses. Signature dishes of the seder meal itself vary according to Jewish communities. While many are also served on the Sabbath and other holidays, some are specific to Passover.

Ashkenazim serve clear chicken broth with dumplings (*kneydlakh*) made from matzo meal and noodles made of egg and potato starch or matzo meal, gefilte fish (poached balls of ground fish), roasted fowl, stewed carrots, and nut tortes made without flour. Because of the limited availability of fresh fruits and vegetables in eastern Europe during late March and early April, carrots, beets, radishes, potatoes, and other root vegetables are important. *Rosl*, prepared weeks in advance by allowing raw beets covered with water to ferment, is the basis for a hot or cold borscht consumed during the week. Delicacies include beet or black radish preserves, *kbremslakh* (pancakes made from matzo meal), sponge cakes, macaroons, and *ingberlakh* (candies made with grated carrot or small pieces of matzo and honey, nuts, and ginger).

Sephardim prepare *haminados*, eggs in their shells braised in water with red onion skins, vinegar, and saffron. Favorite Passover dishes among Moroccan Jews include dried fava bean soup with fresh coriander and stewed lamb with white truffles, which are harvested in February. Greek Jews feature artichokes with lemon, fish in rhubarb sauce, stuffed spinach leaves, leek croquettes, various dishes calling for lamb and lamb offal, and a baklava made with matzo. East European Jews tradition-

ally made their own raisin wine for Passover, while Greek and Turkish Jews made *raki*, a liqueur derived from raisins through a process of distillation. Purchased wine must not only be kosher, which involves many strict religious regulations, but also kosher for Passover.

As if to demonstrate that Passover dietary restrictions are no impediment to innovation and variety, the kosher food industry has developed an astonishing array of Passover products. The historian Jenna Weissman Joselit, in "The Call of the Matzoh," notes that by 1900 Bloomingdales and Macy's featured Passover groceries, wine, and other holiday necessities (Joselit, 1994, p. 221). The most widely observed of the Jewish holidays, Passover occupies only 3 percent of the calendar, but generally accounts for 40 (and in some areas up to 60) percent of kosher food sales in the United States annually. This makes kosher for Passover products an estimated \$2 billion industry. According to *Kosher Today*, a trade publication of the kosher food industry, more than six hundred new Passover products were introduced in 2001 alone, which gave consumers up to four thousand items from which to choose. However, in a world where almost everything is becoming kosher for Passover, from pizza to noodles, Passover may lose some of its culinary distinctiveness.

### Public Seder

Whereas the seder is traditionally a family event, public and organizational seders arose even before the twentieth century in Europe, the United States, and elsewhere to meet the needs of Jewish soldiers away from home (for example, during the American Civil War and today in Israel); Jews confined in hospitals, nursing homes, and prisons; and the destitute. During the twentieth-century, the kibbutz, a collective agricultural settlement in Palestine and then in Israel, created its own Haggadahs and seders, consistent with the socialist and even atheistic tendencies of its founders and the practice of eating together in large public dining halls. During the Holocaust, Jews in Bergen-Belsen, separated from their families, organized to observe the holiday as best they could. Unable to obtain matzo, they determined that *hametz* was permitted and created a special prayer to say over it.

Even before World War I, seaside resorts in the United States attracted Jewish visitors who preferred to avoid the elaborate preparations for Passover and observe the holiday away from home. According to *Kosher Today*, over seventy-five thousand people participated in Passover programs in hotels during 2000 in the United States, and the Passover getaway business, which has grown in size and variety, hoped to fill thirty thousand rooms in 2002. In Israel, many orthodox families spend all eight days of the holiday at a hotel or kibbutz pension to avoid the considerable effort of preparing for Passover. Communal seders are also held in Europe. The first communal seder in Beijing took place in 1998. Caterers organize seders in banquet halls, and restaurants offer seders, in

part as a response to the dispersal of families. Wolfgang Puck, at the prompting of his Jewish wife, began to host Passover seders at Spago, his Los Angeles restaurant, in 1985. The menu features such delicacies as roasted white Alaskan salmon (Panitz, 1999). Peter Hoffman, who has been hosting seders at his Mediterranean-style restaurant Savoy since 1994, created a seder inspired by Marrano traditions. Other restaurants may simply include matzo on the menu.

### Third Seder

Whereas only one seder is required in Israel (and among some Reform Jews) and two seders in the Diaspora, a Lubavitcher tradition holds that the Baal Shem Tov, the eighteenth-century founder of Hasidism, a pietist movement, instituted a Messiah's Feast, mirroring the seder with matzo and wine, on the afternoon of the eighth day of Passover. During the 1920s, Zionist groups and members of the Jewish Labor movement organized third seders, although radical secular Haggadahs, which stressed human agency over divine intervention, were printed as early as the 1880s. In 2002 the Workmen's Circle, which is associated with the Jewish Labor movement, celebrated fifty years of its annual Third Seder, recently renamed A Cultural Seder. Their special Yiddish Haggadah, which makes no mention of God, focuses on liberation struggles and Yiddish cultural achievements. In the late twentieth century, they incorporated elements of the traditional seder for those who only observe this one seder. Other groups, prompted by such crises as Israeli soldiers missing in action and AIDS, also have created a third seder.

### The Christian Seder

There is disagreement as to whether the Last Supper took place during the evening of the fourteenth of Nissan, after the Paschal sacrifice, in the form of a Passover meal (synoptic Gospels), or on the afternoon of the preceding day as an ordinary meal (Gospel of John). Consistent with the former, some Christians reenact the Last Supper as a seder, usually on Holy Thursday, based on practices thought to have been followed at the time of Christ. The Christian seder typically includes lamb, unleavened bread, bitter herbs, *haroset*, *karpas* (raw vegetables), and wine; washing of hands and feet; reclining at the table; recitation of appropriate blessings and passages from Exodus, and singing of Psalms. As Gillian Feeley-Harnik explains in *The Lord's Table: Eucharist and Passover in Early Christianity* (1981), the Last Supper, as a sacrificial meal, "most closely resembles the passover, but every critical element in the passover is reversed: the time, the place, the community, the sacrifice, and ultimately the significance of the meal" (Feeley-Harnik, 1981, p. 19).

### Mimouna

In some communities, a special meal ushers out the holiday or otherwise marks the return to everyday life. Moroccan Jews celebrate the Mimouna after sundown on the

last day of Passover and on the following day with a great variety of post-Passover foods, music, and dance. The earliest record of the holiday dates from the eighteenth century. While the etymology of Mimouna remains unclear, some find a connection with *maimouna* (Arabic, meaning 'wealth', 'good fortune'), *emunah* (Hebrew, meaning 'faith'), and *mammon* (Hebrew-Aramaic, meaning 'riches', 'prosperity'). Some link the timing of the Mimouna with the anniversary of the death of the revered Rabbi Maimon, father of Moses Maimonides, who moved from Cordoba to Fez in 1159/1160. Moroccan Jews believe the holiday originated in Fez.

The evening holiday is traditionally celebrated at home, with doors open to relatives and friends. Ears of wheat and flowers are placed on the table and around the room. A lavish table is set with a white cloth, and depending on the community, symbolic foods may include flour, yeast, wine, five coins, five beans, five dates, five eggs, sweets, nuts, fruits, milk, buttermilk, butter, a live fish, and *mofleta*, the first leavened food eaten after Passover. *Mofleta* is a yeast-risen pancake fried in a skillet, spread with butter and honey, and rolled. In Morocco, where Jews "sold" their *hametz* to their Muslim neighbors before Passover, the Muslims brought the wheat, flowers, dairy products, and other foods to the Jews during the afternoon of the last day of Passover. After Passover, Muslims returned the *hametz* and were rewarded, in addition to receiving a piece a matzo, believed to bring good fortune. The day following Passover is a time for family excursions and picnics. During the Mimouna, a time of courtship, young people dressed in their finery, and betrothed couples exchanged gifts. With the immigration of North African Jews to Israel, other Maghrebi and Levantine Jews also celebrate the Mimouna, which has become a large public event.

Barbara Kirshenblatt-Gimblett

**PASTA.** Ground grain of the wheat plant (genus *Triticum*; family *Gramineae* or grass), native to Eurasia, forms the fundamental component of commercial "pasta," the generic term for what the U.S. Federal Standards of Identity call "macaroni products." Italian commercial dried pasta combines durum wheat (*Triticum durum*, hard wheat, or semolina, its coarsely ground endosperm) and water into a large number of shapes and sizes. Soft or common wheat (*Triticum vulgare*) is used for homemade or "fresh" pasta (which often contains egg, and sometimes oil and salt), as well as for bread and pastries. These are the two most important wheat grains in the Mediterranean diet.

Pasta is a versatile, nutritious, economical, thus democratic, and increasingly international food. In past times, it was fried and sweetened with honey, or tossed with *garum* (fish paste) by the ancient Romans. Or it might have been boiled, or baked in rich pies, called *timballi*, that defied Renaissance sumptuary laws. Today, pasta is usually boiled to a slightly chewy, resistant consistency (*al dente*), and dressed with a variety of sauces, eaten in soup, or baked. The oldest, most traditional Italian condiment from the thirteenth to the nineteenth centuries consisted of butter and cheese (and sugar, cinnamon, and other spices); pasta was also boiled in meat broths. Only since the 1830s was it combined with the

now familiar tomato sauce. In the course of its history, pasta has been both a luxury, and only recently (in the nineteenth century), a popular food.

As late as the 1960s, the people of northern Italy normally ate risotto, polenta, and egg pasta—just as, in terms of fats, butter versus oil divided the cooler North from the warm South. The leveling of traditional foodways has made pasta a truly national food. However, this Italian first course (*primo*) has been adapted to main dish, side dish, salad, and even dessert in its diverse cultural naturalizations.

### History: Dough Versus Pasta

It is vital to distinguish between two classes of pasta in order to make sense of its history. The most ancient form of pasta is flattened dough (Italian *sfoglia*) from which many fresh pasta forms (with and without egg) have evolved. Cereal-derived foods, based on whole, crushed, or finely ground grains, have been common to the Mediterranean for several millennia, taking the primitive form of mush (for example, Roman *puls*). Dough might be kneaded and shaped, and then fried, roasted, baked, or boiled. When it was flattened into a thin sheet and cut into strips, then boiled, a proto-pasta was created. This final step in the process appears to have created the archetypical category known today as “pasta.”

Because a flour dough base is common to both pasta and bread, the histories of these foods have been merged and blurred. Although pasta may seem a simpler food, bread has held a more central place in the Mediterranean and Italian diet and worldview. Were historians to agree upon a common categorization of pasta, based on ingredients and cooking method (boiling in liquid), it might facilitate a clearer distinction between pasta and other forms of dough-based foods.

### Terminology

Dough for boiling evolved into a variety of shapes. The original form appears to have been string-shaped, thread-shaped, worm-shaped, or ribbon-shaped—that is, long and thin, flat or round, as the earliest terms attest. For example, Latin *lāsanum* (earthenware pot, from Greek *lāsanon*, three-footed pot) blended with *lāganum* (a long strip of thin, rolled dough), whence *lasagne*, a plural form in standard Italian. Still today, in Neapolitan or Calabrian dialect, a rolling pin is known as a *laganatura*. Other terms include Latin *tracta* (a long piece of dough, literally, ‘drawn out’), Arabic *itrija* (string-shaped dough, whence southern Italian *trii* or *tria*, and Spanish *aletria*), Italian *vermicelli*, and later, *spaghetti*, *tagliatelle*, and *fettuccine*. Other early forms of pasta were created from small bits of rolled dough (Latin *lixulae*, Italian *gnocco* ‘knuckle’) or stuffed dough (*ravioli*). Standard Italian *maccherone* and dialectal Italian *maccarone* (source of English “macaroni”), an early synonym of *gnocco*, is said to derive from the Indo-European verbal root *mak-* (‘to knead with force’, whence Italian *ammaccare* ‘to crush’, e.g., *macco* fava bean

An American pasta advertisement from the early 1920s showing all the shapes of pasta and macaroni available at that time. ROUGHWOOD COLLECTION.

purée); if so, it testifies to the force required to knead and shape durum wheat dough.

But even the earliest Italian terms for pasta present wide regional variation. Indeed, Italian pasta history has been vexed, enlivened, and bedeviled by profound lexical specificity. One outwardly identical term may designate different things, historically and geographically. For instance, *maccarone*, from its first citation in the twelfth century, has referred to short dry pasta (twelfth century and twentieth century), long dry pasta (southern Italy, eighteenth through the twentieth centuries), long fresh pasta (regional Italian), *gnocchi* (fourteenth through the seventeenth centuries), and even ravioli. And it is not clear whether *lasagne* (*lágana*), widely used by the thirteenth century, were not more like fritters (compare today’s Carnival sweets, *cenci*, *bugie*, *chiacchiere*) than boiled dough.

Pasta means ‘paste, dough, batter’ in Italian. An earlier, now obsolete, term was “alimentary paste,” a loan translation from Italian *pasta alimentare*. Today, a lexical shift makes “pasta” the generic term for which all others stand as subsets, and “macaroni” (Italian *maccarone*/

*maccheroni*) now refers to hollow, short dry pasta, with a few exceptions surviving as regional homemade specialties in southern Italy.

### Origins: East or West

Spontaneously invented forms of pasta existed simultaneously in various parts of the world—East and West—a clear case of polygenesis. Even a cursory look at this basic starch in the food systems of China and Italy, for instance, makes this parallel development obvious. While certain similarities may be surprising (noodles = *tagliatelle*; wonton = ravioli), the differences are no less so. Pasta is eaten by a variety of peoples but in significantly different ways.

The innovative leap—and the part of pasta's history that is more closely associated with Italy—is the revolution that *dry* pasta entailed, in conservation, economy, and diffusion. This process was established by the twelfth century in the Sicilian-Arab world. Thus, only in Italy (and a few parts of Asia) did pasta become so central to diet and cuisine, and such a diversified food. Further, Italy must be credited with pasta's global diffusion.

**Historical landmark versus legend.** A few landmarks mark fixed points in an otherwise fluctuating ocean of pasta history. Alongside such documentation, however, exists a substantial body of pasta mythology, the most notable involving the vexed question of Marco Polo's supposed introduction of Chinese noodles to Italy, likely attributable not to the *Milione* itself (which, however, mentions noodles made from the sago palm tree, enjoyed by Polo in Fanfur, likely Sumatra), but to the October 1929 issue of *The Macaroni Journal* (of the American Association of Pasta Makers), featuring "The Saga of Catay." This legend tells of the encounter of a sailor named "Spaghetti" with a Chinese maiden preparing a strange dish of boiled strands of dough, and of how he divulges this secret to the West. The story evidently sought to create a plausible link between the presence of noodles in China's more ancient civilization (documented during the Shang dynasty, 1700–1100 B.C.E.), and the predominantly Italian identity of pasta in the modern world.

Polygenesis is not a concept that is easily grasped or generally appealing. Italians had been making, consuming, even exporting pasta before Polo's return in 1292, as the earliest document, a Genovese testament predating Polo's return by at least twelve years, clearly attests. Internal evidence further suggests that Polo considered the sago variety a type of pasta, which presupposes the existence of, and familiarity with, pasta as a food. Other data confirms the parallel development of this food in the West.

**Etruscan and Roman.** The Etruscan tomb "La Tomba dei Rilievi," in Cerveteri, fourth century B.C.E., provides iconographic evidence: a woman in the act of rolling out dough, accompanied by familiar implements (for example, rolling pin, sack of flour, water container, knife), al-

though it is not clear how the flattened dough might have been prepared. Horace (*Satires* VI, book I) mentions the comfort of his simple dish of chickpeas, leeks, and *lágana*, whence Salentine *ciceri e tria*, still eaten today; Cicero also speaks of these long strips of thin, rolled dough made with water and flour. Apicius, in *De re coquinaria* (book IV, chapter 2), describes *lágana* fried in oil and tossed with pepper and (that all-purpose Roman condiment) *garum*—a dish of which Petronius's character, parvenu host Trimalchio (in the *Satyricon*), was particularly fond—and *tractae* (evidently dried durum pasta) for thickening broth. He also elaborates on a rich, layered *lágana* dish involving meats, fish, sauce, and spices.

**Sicilian-Arab geographer.** The first clear Italian reference to dried—hence preservable—pasta, and to a pasta industry, comes from Arab Sicily. In 1138, a Moroccan geographer, Abu Abdullah Muhemmed ibn Idris (known as Idrisi in Sicilian), was commissioned by Roger II, the Norman king of Sicily, to survey his kingdom. In his 1154 codex, he describes the vast fields, many mills, and farms at Tràbia (30 kilometers from Palermo), where a stringlike pasta (referred to by its Arabic name, *itrija*) was produced and exported in "shiploads" to Calabria, and to other parts of the Muslim and Christian worlds. The pasta was evidently dry, and a large-scale operation is being described. Although no generic term, hence no notion of pasta, existed in Arab gastronomy at this time, Arabs knew of this dried convenience food—particularly useful for long caravan rides, and later to seafaring Genovese and Sicilian sailors. Beginning in the twelfth century, in fact, Genovese merchants became agents of Sicilian pasta's northward diffusion. By the fourteenth century, they began producing and selling *vermicelli* and other pasta "di Genova"—so that Genoa became, after Sicily, one of the earliest production centers in Italy.

**Genovese barrel of maccheroni.** In the bequest of a soldier, Ponzio Bastone, written by notary Ugolino Scarpa (2 February 1279), a *bariscella plena de macaronis*, a small barrel of dried pasta, is listed. This earliest attestation of the term *macaroni* is important for three reasons: it suggests the value of the food product (for example, worthy of being listed in a will); that it was indeed dry pasta (for example, conserved in a barrel); and that it was, by this date, known as a generic term (as pasta is today).

**Gastronomic utopias: Cuccagna.** In the mythic land of plenty, known to the Italians as *il paese di Cuccagna*, and in medieval Europe as Cockaigne, there was a very peculiar mountain. The Italian version of the myth was first described by Boccaccio (*Decameron*, VIII, 3, Calandrino, a fool's tale). In this gastronomic utopia, which he calls Bengodi, a cauldron sits on top of a Parmigiano-cheese mountain and continuously spews forth *maccheroni* and ravioli that roll down the mountain's side, land in a rich capon broth, and are free for the taking by the poltroons. Such macaroni, however, were evidently synonymous

with *gnocchi*, chestnut-sized or larger balls of flour dough (not potato), often pictured as served on a skewer. This shape accounts for the ease with which they could roll down the *Cuccagna* mountain.

### The Maccheronic Muse

Since pasta has inspired myth, legend, literature, art, film, and graphic design, its history ought take into account historical data as much as its presence in cultural history, for it has a long oral as well as written tradition. Its creation myths have involved the noblest of gods in the Roman pantheon, emperors, and magicians; pasta miracles have promoted worthy candidates to sainthood (for example, St. William the Hermit turned dirt-filled ravioli into a delicious dish); folk narratives often feature magic (pasta) pots; traveler's tales tell of marvelous and strange pasta dishes (for example, Marco Polo); and street theater masks—and actual Neapolitans—have made a public spectacle of pasta. The maccheronic muse has also inspired carnivalesque literature, theater, song, odes, proverbs, and more.

Pasta gave its name to a linguistic/literary phenomenon known as Maccheronic poetry, peaking in the fifteenth century. It was a pastiche of Latin and vernacular Italian, frequently producing a comic effect by borrowing a vernacular term that reflected the rustics, who, in turn, were referred to by the gross and simple food they ate, *maccherone* or *gnocco* (noodle-head), and who spoke no Latin, the language of culture. The most notable example of this tradition is the Maccheronic poet, Teofilo Folengo (alias Merlin Cocai), author of the mock-heroic epic *Baldus*, in which pasta-maker muses reside on Mount Cockaigne, and whose genius is attributed to the consumption of *maccheroni* and *lasagne*.

### Eighteenth-Century Naples as Pasta Capital

Naples began to import pasta from Sicily at the end of the fifteenth century, but it was not until the eighteenth century that Neapolitans earned the title of *mangiamaccheroni* (macaroni-eaters)—a title earlier borne by Sicilians. Naples became the emblematic capital of pasta, and the city's representative was the *commedia dell'arte* character, half-starved Pulcinella, who on stage was always eating or talking about macaroni. By 1785 there were 280 pasta shops in Naples. Pasta became a street food and its most devoted consumers were street people—*lazzaroni*—as seen in myriad popular prints of the time, where they are characteristically portrayed holding the long strands, dressed with Romano cheese, with their fingers, and at arms length sliding them, often unchewed, down the gullet. Indeed, so unique was this spectacle that it became a must-see tourist attraction, and gentlemen on the grand tour often ordered up a plate of pasta for a *lazzarone*, just to see it performed.

### Immigrants and Pasta

Neapolitans and other southern Italians were critical to pasta's diffusion throughout the world. For it was as much

immigration—and the majority of immigrants were, in fact, Neapolitan and southern—as technological advances and transatlantic trade, that brought pasta to the world's attention. Along with the wave of late-nineteenth-century immigrants came shiploads of spaghetti in blue wrap (for example, Napoli Bella and Vesuvio brands), olive oil, and condensed tomato paste. Americans first considered these inedible foreign foods and tried to reform the newcomers' diet, but spaghetti won out and eventually became American, not merely ethnic, fare. Italian immigrants were to introduce many other cultures to pasta wherever they settled.

Although Thomas Jefferson, much interested in macaroni and pasta technology, brought cases of the foodstuff to America in 1786 (and later had a pasta machine shipped to him from Campania), it was not until 1848 that it began to be produced commercially in America. The World War I years and the interruption of pasta imports from overseas gave rise to an expanded pasta industry in the United States, as many Italian-American pasta importers became manufacturers, through small family operations, many of which still exist. Prohibition may have given pasta a boost as well, since it seemed a logical accompaniment to speakeasy wine. In the expanding pasta industry of the 1930s, pasta ceased to be merely Italian and became an American food.

### Pasta as Emblem

Ethnic stereotyping frequently makes reference to food. Italians have long been associated with pasta, and Italians from different regions represent themselves by the type of pasta they eat. In England, from approximately 1750 to 1850, a "macaroni" referred to a foppish Englishman, a dandy, who affected foreign (Italian) style by overdressing, wearing a preposterous wig, and perhaps eating foreign foods (for example, *Yankee Doodle Dandy* who "stuck a feather in his hat and called it macaroni" and the London gentlemen's club, The Macaroni Club). On the negative side, a cultured Italian might have referred to a simpleton or country bumpkin as a *gnocco*, *maccherone*, or *spaghetto*. Sicilians—later Neapolitans—were derogatorily labeled *mangiamaccheroni* (macaroni-eaters) by Italians farther north. Americans have referred to Italians as "Spaghetti Benders." And Marinetti's Futurist Manifesto did not help matters when it declared war on traditional foods, especially pasta, a food which, the avant-garde insisted, promoted moral and physical laxity. The ideal, evidently, was the Germanic meat-eater, a virile warrior race. Italians ignored the Futurists' cultural violence. Instead, Mussolini waged a battle on wheat (*battaglia del grano*) in an attempt to make Italy wheat-sufficient. The vastly increased wheat acreage had the effect of shifting the epicenter of production northward (pasta producers included Agnesi in Oneglia, Buitoni in San Sepolcro, Barilla in Parma), thereby ending the dominance of Naples by the 1940s.

Many legendary Italian pasta-eaters have helped raise the image of this food: Rossini, Caruso, Sophia Loren. Pasta iconography, old and new, traces its presence in cultural history, from early popular prints of *Cuccagna* or of Neapolitan pasta-eaters, to pasta advertisements, packaging, and film (for example, Charlie Chaplin in *City Lights*, Disney's *The Lady and the Tramp*, and in Italy, Totò, Sophia Loren)—all of which molded pasta's image for millions.

### Commercial Pasta: From Artisan Guilds to Multinationals

From the fourteenth to the sixteenth centuries, pasta became well established all over Italy. Pasta makers became so numerous that they formed corporations and guilds, largely to protect their interests against competing guilds (for example, bakers). These guilds were in Florence (*lasagnari*), 1337; Genoa, 1574; Savona (*fidelari*), 1577; Naples (*vermicellari*, *pastai*), 1579; Palermo, 1665; Rome, 1642.

It is in the passage to dried pasta that the quantum historic leap is achieved and pasta commerce begins, the earliest record of which goes back to medieval Arabs and Sicilians. In more recent times, increasingly efficient technology relating to the basic phases in pasta production—kneading, pressing, extruding, cutting, and drying—together with improved distribution networks and power sources (electricity), have led to an enormous increase in production and consumption. Indeed, by the mid-twentieth century, commercial pasta had truly become a universal food for all classes.

Large-scale pasta production first flourished in coastal areas (Palermo, Genoa, later Naples) where plenty of sun, and alternating warm and cool sea breezes allowed for outdoor drying—the most critical part of the process—and also made shipping easy. Like laundry, spaghetti was hung to dry on outdoor lines and became part of the Neapolitan folkloric milieu. Pasta brands from Gragnano and Torre Annunziata, where warm Vesuvian air and cool sea breezes created perfect drying conditions, became renowned. Once artificial drying technology was devised, however, manufacturing was freed from such climatic considerations.

Other technological milestones included mechanical kneaders, continuous feed presses, even refinements of the fork. Cesare Spadaccini of Naples invented the first mechanical kneader to replace feet (although this was not developed), as well as a four-prong shortened fork to make spaghetti twirling easier and its consumption possible at the Neapolitan court of Ferdinand II (circa 1840). But it was a spate of mostly nineteenth-century inventions that revolutionized the industry: for example, Féréol Sandragné's prototype of the "continuous" feed machine, and the "Marsigliese," a mechanical sieve that could sort crushed grain.

Early artisans' guilds and small family-run businesses have largely given way to multinational giants who count pasta manufacturing among their diversified holdings and enjoy large market shares of a lucrative, expanding global market. Some of these companies are the following: Borden (largest pasta producer in the United States, sole U.S. distributor for De Cecco since 1988, and head of an empire of small, regional companies); Philip Morris (parent company of General Foods, acquired Kraft in 1988); Nestlé (acquired Buitoni in 1988); Hershey's; Campbell's; and Lipton.

### Wheat

Sicily and southern Italy—ancient Rome's, then Italy's, breadbasket—was an early source of durum wheat for Italian pasta, which, since 1967, has been the only legally mandated grain allowed for this food. While Italians came to produce and consume the world's largest quantities of pasta outside Asia (over fifty pounds per capita in 1988), Italy's capacity to produce wheat was easily overwhelmed. In the nineteenth century, other sources were added. Genovese merchants imported the best Kubanka wheat (up to 19 percent protein), grown in the fertile black earth of Taganrog, Crimea, on the Black Sea. But famines, revolution, and genocide had destroyed this mythic Russian wheat by the 1920s and 1930s, apparently forever. North American wheat from Manitoba and North Dakota filled the vacuum. American durum wheat production—which, in turn, boosted the American pasta industry—was largely due to the efforts of one man. Mark Carleton, an agronomist for the U.S. Department of Agriculture and an expert in plant pathology, went to Russia in 1898 looking for rust-resistant wheat and, upon returning, converted farmers, milling companies, chemists, and hotel and restaurant cooks to accept durum wheat.

### Pasta Typology: Cutting the Linguistic Dough

Estimates of the number of pasta shapes range from 600 to 1000. Pasta atlases are only recently beginning to appear. The sheer volume of regional, traditional, and also industrial and historical types—although only a fraction of them remain in common use—makes this task a daunting one. Some of the earliest terms refer to length and thinness, for example: Arabic *itrija* and *sev* or *seviyan* (from Hindi *sevika* 'thread'), Italian *vermicelli* ('small worms', originally, finger-length), and later, Italian *spaghetti* (from *spago* 'string'). Other terms refer to the dough and to shaping techniques that involve cutting (Italian *tagliatelle*, from *tagliare* 'to cut'), rolling, or stamping. Greatest variation occurs in commercial, not home-made pasta, for the obvious reason that industrial dies have made such innovations possible.

**A raviolo by other names.** The language of pasta (as of music) is Italian. Much of its rich lexicon is attributable to the richness of the Italian language itself. There are suffixes, given in their plural forms here, that can reduce

its dimensions (-elli, -etti, -ini, -otti, as in *ravioli/ravioletti* and *tortelli/tortellini*), or increase its dimensions (-oni, as in *ravioloni, tortelloni*), or subtly grade it by increasing width (*tagliolini* > *fettuccine* > *tagliatelle* > *pappardelle* > *lasagne*). There is also rich regional variation. For example, the case for filled pasta (of which Emilia-Romagna is the heartland) is known as *casoncelli* (*cansonsei*) in Bergamo, *tortelli* in Emilia-Romagna, *agnolotti* in Piedmont, *pansoti* in Liguria, *cappelletti* or *ravioli* in central Italy. As for the most common homemade ribbon-shaped egg pasta, *tagliatelle* are also known (with slight variation in size) as *fettuccine, lasagnette, trenette*.

Still today, a marked distinction exists between egg-based fresh pasta, a special, often festive food, and dried commercial pasta, daily fare. But Italians also divide pasta as follows: pasta in clear broth (*pastina in brodo*); pasta in heartier vegetable soup (*minestra*, whence *minestrone*); dried pasta drained and served with a sauce (*pasta asciutta*); and baked pasta (*pasta al forno*: for example, *lasagne, timballo, pasticcio*).

Pasta typologies might further be ordered according to varying criteria: method or place of preparation (home, restaurant, factory); grain type (soft, durum, whole, alternative); calendrical occurrences (festive versus penitent pasta, for example, with and without meat sauce or eggs); Italian versus non-Italian or emigrant pasta (for example, Italian-American spaghetti and meatballs); and finally, pasta morphology. Pasta can even be classified according to consumer profile, age, cultural background, and health concerns. For instance, adult pasta differs from children's varieties: there is Italian nursery food, *pastina in brodo* (tiny pasta in clear broth); American macaroni and cheese and canned dinosaur or alphabet pasta; and pasta on toast for the British. Special pastas have been developed for the wheat intolerant; and gourmet pastas are aimed at the high-end market. Homemade pasta can be further classified according to the instrument used: rolling pin versus pasta maker or small press (for example, a *torchietto* for extruding *bigoli* in the Veneto); a "comb" or *pettine* (for example, for *garganelli* in Romagna); a zither-like instrument, known as a *chitarra* (guitar), over which thin dough is stretched and rolled to produce thin strands (for example, for *tonnarelli*, resembling square spaghetti, in the Abruzzo); a long metal rod or *ferro* (for long *maccheroni* in Calabria, Puglia, Sicily).

Then there is morphology—long versus short, smooth versus ribbed, hollow versus filled, straight versus fluted. The myriad shapes draw on many semantic areas—human, natural, and even divine. There are helixes, tubes, shells, pearls, nests, worms, butterflies, snails, birds, stars, moons, waves, threads, ribbons, bowties, even "priest-stranglers" (*strozza-* or *strangolapreti*). Paternosters and avemarias (resembling rosary beads), and other shapes inspired by politics (*garibaldini, mafalde, tripoline, assabesi, abissini*), are no longer made. But innovation continues, even though some shapes prove to be mere fads (for example, radiators, UFOs).

Matching pasta to sauce, determining pasta to sauce ratio, and knowing the correct cooking time are subtle areas of pasta connoisseurship, traditional for Italians but learned by others (although traditional canons are shifting even in Italy). In a fifteenth-century cookbook, *De honesta voluptate ac valetudine* (Of honest pleasure and well-being), Bartolomeo Sacchi (pseudonym Plätina) cautioned that pasta should be cooked "for as long as it takes to say three paternosters"—a short amount of time, even for fresh pasta.

## Trends

Pasta trends take place within wider social and nutritional contexts. There has been a move toward whole foods and alternative grains such as corn, buckwheat, and spelt. Innovative ingredients—some restaurant-driven—include colored pasta (tomato, herb, beet, mushroom, shrimp, even chocolate) and novelty-stuffed pasta (seafood, artichoke, dried tomato). There has also been a trend toward fusion cuisines, for example, blending East and West. New health guidelines advise lower fat, higher fiber, increased vegetarianism, less processing. The American trend toward greater convenience favors ready-cooked, frozen, microwaveable, and cold-serve pastas, although the Slow Food movement is beginning to counter this trend in the new millennium. Americans are becoming more sophisticated in regard to better quality products, taste, nutritional value, authenticity, seasonality, and the artisan tradition.

## Nutritional Value: Fat or Skinny?

Pasta's fortunes have fluctuated over its long history: it has been considered both a luxury food (in the sixteenth century, Neapolitan authorities prohibited its consumption in times of famine or scarcity of wheat) and a vernacular staple. Commonly perceived as a poor man's food at the beginning of the twentieth century, pasta began, with the support of nutritionists extolling the virtues of the Mediterranean diet in the 1970s, to experience a rehabilitation. New nutrition guidelines (and the food chart reformulated in the 1990s) recommend less protein, less saturated animal fat, more fiber, and more complex carbohydrates. Pasta, therefore, is now recognized to be a healthy food. It is also a highly versatile, immediately satisfying food, recommended for athletes ("carbo-loading" sustains energy before strenuous sports) and even for refined palates.

Vegetables, lean meats, or fish, combined with good quality (even enriched or whole wheat) pasta, makes an excellent, balanced meal. Components of pasta include moisture (water), energy, protein, fat, carbohydrates, and ash. According to the U.S. Department of Agriculture bulletin (1981), nutrient values for one cup of spaghetti (two ounces uncooked) are approximately seven to fourteen grams of protein, thirty-nine grams of carbohydrates, and when enriched, it provides calcium, phosphorus, iron, potassium, thiamin, riboflavin, and niacin.

The caloric value of one cup of cooked pasta is approximately 190 calories (if *al dente*) and 155 (if tender).

Luisa Del Giudice

**PASTEUR, LOUIS.** Coupling true scientific genius with a talent for dramatic self-promotion, Louis Pasteur (1822–1895) rose from humble beginnings as the son of a tanner in a small French village to international fame before his death.

Pasteur was trained as a chemist, and his earliest work on the crystals of tartaric acid, a naturally occurring by-product of wine production, caught the attention of several established chemists, who promoted his career and helped him secure an appointment as professor of chemistry at the University of Strasbourg.

Arriving in Strasbourg in January of 1849, he met Marie Laurent, daughter of the university's rector. With characteristic decisiveness, Pasteur proposed marriage within a few weeks, and in May of that year he and Marie were married. He chose well: For the rest of his life, Marie Pasteur supported and assisted him in his work; often they spent their evenings together, with Pasteur dictating notes or letters to his wife.

The Pasteurs moved in 1854 to the university at Lille, a thriving industrial area of France. Pasteur encouraged the practical application of science to the industries around him. His efforts on behalf of a local manufacturer who made alcohol from sugar beets were his first serious study of fermentation.

Moving on to Paris, he assumed positions at his old college, the Ecole Normale Supérieure, and later at the Sorbonne as well. He was not provided with a research laboratory, so he set one up at his own expense in a cramped unused space. This included a compartment under the stairs so small that he had to crawl in on his hands and knees to check his cultures.

In 1863, Emperor Napoleon III asked Pasteur to assist France in combating various “diseases” of wine that often caused exported French wine to go bad before it reached its destination. Pasteur believed that the yeasts observed in wine were the cause of fermentation, a fact that was not understood by much of the scientific community. These living yeasts appeared so mysteriously that many chemists believed they were generated spontaneously. Pasteur devised ingenious experiments to demonstrate that the yeasts came from the atmosphere. His belief in germs as causative agents that could infect a new medium on contact was sustained in his later work with animal and human diseases.

Pasteur also observed that other microbes besides the wine yeasts were present whenever the wines soured. In

fact, he and his assistants soon learned to predict the taste of a wine according to which microbes they spotted in it with their microscopes. Pasteur urged the winemakers to provide conditions conducive to the growth of wine yeast and not to that of other microbes. He suggested a prolonged gentle heating, which discouraged undesirable microbes without altering the taste of the wine. A jury of wine experts conducted a taste test at Pasteur's request to establish that the taste was unaffected by the heating. This technique, which is today regularly applied to all kinds of foodstuffs, especially milk, quickly came to be called "pasteurization." Pasteur took out a patent on this process, but he soon allowed it to pass into the public domain. Though less dramatic than his later work with diseases, pasteurization is perhaps Pasteur's greatest contribution to the safety of food throughout the world. Pasteur was not the first to preserve foods by heating and protecting them from contamination, but he extended the practice to a variety of foodstuffs and offered a theoretical basis for its success.

Pasteur also advised vinegar makers, as well as the French beer industry. He hoped to make French beer superior to German as a gesture of revenge for the Franco-Prussian War of 1870. He taught hygienic practices to France's silk industry and, less easily, to the medical profession. The germ theory was then successfully applied to the development of vaccines for anthrax and other animal diseases, and finally to prevent the development of the dread rabies in human beings.

Pasteur achieved all this by dint of persistent hard work. His was not a balanced life. His labors, his ambition, and his aggressiveness in promoting his theories and reputation may all have been culprits in his severe stroke at age forty-five, which paralyzed his left side and left him with a limp. However, he continued to work for another two decades before his increasingly frail health gradually slowed him down.

Despite stirring up a good deal of controversy, Pasteur was given many honors in his lifetime. He received scientific prizes and awards and was elected to the French Academy of Sciences, the Academy of Medicine, and finally the august Académie Française. In 1888, the private Pasteur Institute was established in Paris, funded by contributions large and small from all over the world. Pasteur's seventieth birthday was the occasion for a national jubilee, and at his death he was given a state funeral in Paris before his body was interred in a grand tomb at the Pasteur Institute.

Even before his death, Pasteur was regarded, especially in France, almost as a secular saint. His earliest biographies were hagiographic, in keeping with the preference of the late nineteenth and early twentieth centuries for heroes of mythic proportions. The current age, on the other hand, needs to debunk, demythologize, and deconstruct the legends of the past. Accordingly, a modern reassessment of Pasteur has been in progress since the late twentieth century, aided by material from Pas-

teur's private laboratory notebooks, which have been available to scholars only since 1971. In the end, when all the evidence is gathered and reconsidered, the popular view of him may be altered, but Pasteur will remain a human being whose unceasing effort, scientific imagination, and inspired intuition unquestionably improved the food we eat and the world we live in.

**PASTRY.** Pastry is flour mixed with shortening and flavoring ingredients to produce a coherent mass, used for pies and other dishes in North American, European, and Middle Eastern cuisines. Basic additions are fat, a little salt, and water. Pastry-making, *pâtisserie* in French, has developed as a special branch of cookery. Specialized products of the pastry cook or *pâtissier* include delicate flour and sugar confections (cakes, cookies, waffles, meringues, frostings, glazes, and fillings) combined in small pastries for snacks, taken with tea or coffee or after meals. By extension, the word pastry is sometimes used collectively to indicate sweet, flour-based items for dessert.

Defining pastry types is difficult, as there are numerous variations. Three basic ones are short-crust or pie pastry, puff pastry, and flaky or rough puff. Short-crust pastry is one part fat (butter, lard, or commercial pastry fat) to two of flour by weight. The fat is cut or rubbed into the flour until the mixture resembles breadcrumbs, a little ice

water is added, and the mass is pressed together with minimal working to make a dough. French *pâte brisée* is similar, but uses a little more fat and is mixed with egg. Variations include sweetened *pâte sucrée* and *pâte sablée* (very rich, similar to cookie dough). Short pastries are crumbly when cooked and used for many pies and tarts.

Puff pastry or *pâte feuilletée fine*, is an elaborate, layered pastry with a tender melting texture and excellent flavor. Equal proportions of butter to flour by weight are used. About a fifth of the butter is cut into the flour, and water is added to make a dough. This is allowed to rest in a cool place, and then rolled out; the remaining butter is then placed as a block in the center of the sheet of dough, which is folded over it. It is rerolled and folded in three, a process known as a “turn.” Four turns are made with rests between, giving a dough with thin, even layers of fat between leaves of dough; air pockets also get trapped in the layers. Well-made puff pastry has up to 240 layers, and expands up to eight times its original

thickness during baking. It is used for napoleons, cornets (cone-shaped pastries often filled with whipped cream or ice cream), and other fine pastries, sweet or savory, in the French tradition. Yeast-leavened doughs are turned with butter in the same way to make croissants and Danish pastries.

Flaky or rough puff pastries, French *demi-feuilletées*, are less well-defined. They usually have fat-to-flour ratios that are higher than that of short-crust but lower than that of puff pastry. They are made with the general method used for making puff pastry, but the butter may be spread over the dough in one batch or incorporated in three fractions, one each time the dough is turned. Quick versions are made by cutting the fat into pea-sized lumps, adding water to make a dough, and then giving it three or four turns. The dough has a light and layered effect but does not rise as high as puff pastry. It is also used in similar ways, especially with meat dishes such as beef Wellington.

Many other pastry recipes exist. *Choux* pastry uses a very different method. Water and butter are heated together; the result is mixed with flour, and eggs are beaten into the mass. The paste produced is soft and supple, and is piped to make cream puffs, chocolate éclairs, and other shapes, or flavored with cheese for the French *gougère*. English cookery includes hot-water crust: water and lard heated to the boiling point and mixed with flour, giving a malleable, strong paste that is raised while hot to make tall pies of pork or game; and suet crust, made of flour, beef suet, and water, and used for suet puddings and dumplings.

In Central Europe, the Middle East, and North Africa, strudel and phyllo pastries are made from a dough of flour, a little butter or oil, and water, which is worked to form an elastic mass that is stretched into a paper-thin sheet. When the pastry is ready for use in baking, its surface is brushed with melted butter. Strudel pastry is rolled around fillings such as apples or poppy seeds, while phyllo is often cut into sheets and stacked in layers with nuts to make sweet dishes, or with spinach and cheese for savory ones.

Indian cookery involves pastry made from flour with a little ghee (clarified butter) or oil. This is used to enclose savory fillings for *samosas* (turnovers), and is deep-fried, providing the crispness that baking gives to pastries from the European traditions. Some types are cooked alone and drenched in sugar syrup to give sweet pastries. Chinese cookery also includes a few plain short-crust-type pastry recipes, notably that used for moon cakes, filled pastries traditionally eaten to celebrate the Moon (or Mid-Autumn) Festival.

Protein content of the flour is important: too much, and the pastry is tough and shrinks; too little, and it is very mealy. A medium protein content is best. Development of gluten (the protein complex that gives texture to bread) is inhibited by cutting in the fat, a process which

Vienna still reigns as the capital of fine pastries. These pastries, ornamented with strawberries and kiwi fruit, were displayed in the window of Janele's Bakery in Vienna, one of the well-known pastry shops in the city. © WOLFGANG KAEHLER/CORBIS.

The pastry shop became a social institution by the end of the nineteenth century. This painting of the Gloppe Pastry Shop by Jean Béraud in the Musée Carnavalet, Paris, provides a vignette of the dainty snacking once associated with these elegantly appointed establishments. © ARCHIVO ICONOGRAFICO, S. A./CORBIS.

coats the flour particles, preventing the water from reaching the proteins. In flaky and puff pastries, turning encourages limited gluten development in horizontal sheets for the characteristic texture.

Fat choice is also important. Butter gives a good flavor but produces a less short texture than lard, which gives a flaky texture. Lard has a coarse crystal structure that coats the flour particles more effectively and is one hundred percent fat, unlike butter, which contains a little water. Some cooks consider a mixture of lard and butter to give the best balance of flavor and texture. Margarine and specially tailored vegetable fats are often substituted on grounds of cost, nutrition, or ethics. Oils give very crumbly pastry. Keeping pastry cool during working is also important, otherwise the fat becomes oily and the texture suffers.

During baking, the water in pastry vaporizes and allows crisp flakes of dough to form. In puff pastry, water vapor and air trapped between the layers expand and force them apart, making the pastry rise; a similar effect produces the characteristically hollow texture of *choux* pastry.

The history of pastry has been little explored. Pastry of a sort was known to both Greek and Roman civilizations, but it was oil-based, and limited in its applications. Late medieval references to pastry do not make it clear what type is being referred to. In the seventeenth century, the work of La Varenne (originally

published in 1651) and others shows that several types of pastry were recognized. Methods for puff pastry had developed, as had pastes rich with butter, cream, or eggs, used for little tarts and pies. These were intended to be eaten, unlike the coarse puff paste made for great pies, which was plain, made from brown rye flour with only a little fat. It protected game and meat fillings from intense heat during cooking, and acted as a container that excluded air and preserved the contents afterwards. By the nineteenth century, pastry making was a complex art, recorded by chefs such as Jules Gouffé who moved between the great houses of Europe, learning and codifying techniques from different places. Pastry had also developed as a traditional product in certain areas, such as Cornwall in England, where Cornish pasties, semicircular turnovers filled with meat and vegetables, had become a traditional food for miners.

The ingredients of pastry make it an energy-dense food, and the use of fats such as butter and lard gives it a high cholesterol content, but it is so important and convenient as an edible container that it seems likely to remain popular. Many types of sweet pastry that were developed were intended to be treats, not everyday food; it is only the abundant wheat and fat production of modern agriculture that has made them so accessible.

**PEANUT BUTTER.** Peanuts (*Arachis hypogaea*), also widely called "groundnuts," originated between southern Bolivia and northern Argentina. In pre-Columbian times, they were found throughout Brazil, Peru, Mexico, and the Caribbean. Early in the sixteenth century, European explorers transported them to Africa and Asia. From the beginning, peanuts were ground into paste and used as a flavoring in soups, stews, and other dishes.

Through the slave trade, peanuts were introduced into the British North American colonies. Slaves grew peanuts in their gardens and introduced them into mainstream cookery. Hand-ground peanuts appeared as an ingredient in American recipes by the 1830s.

### John Harvey Kellogg

Ground peanuts were a minor product until popularized by John Harvey Kellogg, the vegetarian director of the Seventh-Day Adventist Sanitarium in Battle Creek, Michigan. In 1894 he created a process to make "nut butters," which were intended as a substitute for cow's butter and cream. Peanuts were the least expensive "nuts" available, and the product made from grinding them was promptly called peanut butter. It was served to members of America's elite who visited the sanitarium, and vegetarians began selling it in small batches. Kellogg's new culinary treat spread throughout the United States and, subsequently, the world. Kellogg decided not to patent the process for making peanut butter, but he did create the Sanitas Nut Food Company to sell his nut butters.

Peanut butter quickly became a fad among health food manufacturers in America. Vegetarians adopted it almost immediately, and recipes for making it appeared in vegetarian cookbooks beginning in 1899. Vegetarians employed peanut butter for many purposes, but particularly for making mock meats or meat substitutes that purportedly imitated the appearance and taste of such diverse products as chicken, veal cutlets, tenderloin steak, oysters, and meat loaf.

## Mainstream Peanut Butter

Peanut butter quickly spread into the culinary mainstream and was employed as an ingredient in salad, fudge, biscuits, muffins, cookies, and breads. A major early use of peanut butter was for making sandwiches, which were initially flavored with a variety of ingredients, such as mayonnaise, cayenne, paprika, nasturtiums, cheese, watercress, meat, Worcestershire sauce, and cream cheese. Recipes for peanut butter sandwiches proliferated throughout the early twentieth century. The first known reference to combining jelly with peanut butter was published in 1901. During the early 1900s, peanut butter was considered a delicacy and, as such, it was served at New York's finest tearooms.

## Commerce and Industry

Initially, peanut butter was made by grinding a few nuts at a time in a mortar and pestle. As this was a slow and difficult process, it was unlikely that peanut butter would ever have become a major culinary product. It was at this point that technological innovation intervened, and converted a food fad into an industry. Commercial peanut butter made its debut in 1896. Before the development of special grinders, the peanuts were ground in adapted meat grinders. The peanut butter was manufactured in small quantities by individuals and sold from house to house; then small factories sprang up, and peanut butter became a familiar article on grocers' shelves. The first recorded peanut butter trademark was granted to the Atlantic Peanut Refinery in Philadelphia in December 1898. The recipe consisted only of ground peanuts with salt added. By 1899, an estimated two million pounds of peanut butter were manufactured in the United States. The largest producers were located in the South and the West. By 1929, there was hardly a city that did not have one or more peanut butter factories, and its consumption during the next five or six years equaled that of all preceding years combined.

Peanut butter sandwiches moved down the class structure as the price of peanut butter declined. After the invention of sliced bread in the 1920s, children could make their own sandwiches without using a sharp knife. The combination of these two factors helped make peanut butter sandwiches one of the top children's meals in America. Beginning in the 1920s, manufacturers lobbied school cafeterias to buy inexpensive peanut butter. Its flavor was liked by children, and minimum time and equipment were required to prepare it. However, peanut allergies among children have recently been on the rise, and peanuts and peanut products have been banned from some schools.

Today, three major peanut butter manufacturers dominate the market: Skippy, created by Joseph L. Rosefield of Alameda, California (first produced in 1932); Peter Pan peanut butter, manufactured by the E. K. Pond Company (Pond, a subsidiary of Swift & Co., began making peanut butter in 1926); and Procter & Gamble's Jif

(first produced in 1958), whose plant in Lexington, Kentucky, is the largest peanut-butter-producing facility in the world.

### **Peanut Butter as an American Icon**

Peanut butter was initially considered a health and vegetarian food, but it quickly became a major mainstream staple, a mass-produced commodity sold in almost every grocery store in America. It was employed on virtually every type of food from soups, salads, sauces, and main courses to desserts and snacks of every description. Few other products in American culinary history have achieved such influence in so many ways in such a short period of time, and peanut butter has remained a staple food in America ever since.

Peanut butter has been employed in a number of other commercial products—cakes, confections, cereals, and many snack foods—the most successful being in the manufacture of chocolate bars. In 1928 H. B. Reese Candy Company produced a chocolate-covered peanut butter cup, which subsequently became known as “Reese’s Peanut Butter Cup.” Two years later, Frank and Ethel Mars introduced the “Snickers Bar,” a combination of peanut butter nougat, peanuts, and caramel encased in milk chocolate. Snickers quickly became America’s most popular candy bar, a position it has held ever since. Chocolate and peanut butter are combined in some of America’s best-selling chocolate bars, including Snickers and Reese’s Peanut Butter Cup.

Peanut butter cookbooks have been regularly published since William Kaufman’s *“I Love Peanut Butter” Cookbook* was published in 1975. The Adult Peanut Butter Lovers’ Fan Club currently counts over sixty thousand members. Today, Americans consume annually about 857 million pounds of peanut butter, or 3.36 pounds per person. It can be found in 83 percent of American households. Peanut butter is also consumed in Saudi Arabia, Canada, Japan, Korea, and Western Europe.

**PEANUTS.** See **Legumes; Nuts; Oil; Peanut Butter.**

**PEAS.** Peas are among the oldest cultivated vegetables and once served as a dietary cornerstone for the early agrarian societies of Europe and the Middle East. The English word for pea derives from Latin *pisum*, a term that now serves as the name of the genus to which peas belong. Pea is thus used in English in two senses: as a descriptor for other pea-like vegetables, such as cowpeas, chickpeas, pigeon peas, and winged peas; and as the specific name for *Pisum sativum*, the peas employed by humans as food or for such agricultural uses as fodder and green manures.

### **Genetic Origins**

All true peas belong to the same species, but are divided out into three distinct groups or subspecies. This means that even though peas are self-fertile, they readily hybridize in nature and as a result, there are numerous crosses that often blur the differences between the subspecies. This discussion will focus exclusively on the three subspecies and their historical uses as a source of food.

The genetic origin of peas is thought to be southwest Asia, somewhere in the vicinity of Afghanistan. The ancestral pea is now extinct, although its immediate descendants, the wild pea (*Pisum sativum*, spp. *elatius* and spp. *humile*) survive in the Middle East. This is a vining plant with tiny flowers (often crimson or rose) that rambles over rocks or climbs on low bushes for support. Like modern peas, it has tendrils that allow it to use the limbs of nearby plants so that the pods are raised up and out of reach of rodents and other small animals. Stone Age sites in Greece and coastal Turkey dating from about 5700 B.C. have yielded carbonized remains of the *elatius* subspecies, whereas sites from the same period more inland in present Israel and especially the Tigris Valley, have produced remains of the subspecies *humile*. The general conclusion is that wild peas were recognized for their food value at an early date and were gathered both as a fresh vegetable in June (when the seeds are green and sweet) and as a dry seed for use during the rest of the year.

Wild peas later appear in the remains of Swiss lake dwellings (about 3000 B.C.E.), so it is evident that they were carried out of their native habitat into Europe and maintained either as a cultivated plant or as a managed plant in the wild. Since the pea formed a dietary triumvirate with lentils and such ancient grains as emmer,

Advertisement for the Wordsley Wonder, a marrowfat pea introduced in 1888 by Webb & Sons of Stourbridge, England. Where Americans have developed a passion for tomatoes, the English have taken their passion for peas even farther. Between 1700 and 1900, the English developed over a thousand varieties of peas, and perfected methods of growing them in large fields, as seen in the background of this woodcut. ROUGHWOOD COLLECTION.

einkorn, and barley, it is likely that peas traveled as a useful weed along with the migration of early grains. Archaeological evidence suggests that wild peas were commonly found in areas planted with grain and that the entire plants were harvested, hung up and dried, then threshed as needed. Wild peas were mashed and cooked alone or with grains to make porridges, or they were ground into flour and mixed with other flours to make flat breads. Pea flour was also used as a medicine, especially in the treatment of wounds.

### Cultivated Peas

The next step in the evolution of the pea was the appearance of the field pea, which is written botanically as *Pisum sativum*, spp. *arvense*. This is a form of pea that evolved artificially through human intervention and supplied early agricultural societies from China to Ireland with one of the most important staple foods down to the eighteenth century. Pease pottage was a common dish in the Middle Ages, and in India, *vatana* (dal made from peas) is still an important element of everyday diet. In

the southern portion of the United States, people commonly refer to cowpeas as field peas, but the practical point is clear: this is not a plant grown in kitchen gardens; it is an American substitute form for the true field peas of Europe. Field peas, like wild peas, were harvested on the vine and dried in the barn. The peas were threshed as needed and the straw given as fodder to the livestock.

There are many heirloom varieties of field peas surviving today, although they are grown mostly as fodder or as a green manure (plowed under to enrich the soil). In the Middle Ages they were food for man and beast, and it is this type of pea that was introduced into China from India during the T'ang Dynasty. Pea soup even appears in early Buddhist texts as a healthful, albeit simple dish consistent with a monastic lifestyle.

Regardless of where they are cultivated, all field peas share certain common features that separate them from the so-called garden peas which later became more important. The vines are generally shorter and stronger than those of wild peas, the plants are more compact, and through natural mutation and careful selection over time, they normally yield a higher number of pods often with large seeds. However, to the casual viewer, the most distinctive feature is the flower, which is multicolored. Some of the most beautiful flowers in this species appear on field peas. Furthermore, the dry seeds are normally speckled. The tiny, speckled Jämtlands Grä Förder Ärt of Sweden, and the tan-seeded Groch Pomorski (Pomeranian Pea) of medieval Poland are two surviving examples of this type.

Field peas are often referred to in horticultural literature as gray peas, a term that seems to have evolved in the low countries owing to the color of the seed and the flour they yield. During the late Middle Ages, Capuchin monks in Holland and northern Germany devoted considerable energy to the improvement of field peas for agricultural purposes. This has resulted in a group of large-seeded gray peas referred to as Capuchin, especially those from the Netherlands where the breeding of new pea varieties became a national pastime by the early 1600s. One of the classic peas from this group and one which dates from the 1500s is the handsome blue pod Capucijner, a soup pea growing on six-foot (two m) vines.

### Garden Peas

Dwarfism is a recessive gene in peas, and every so often short plants will appear in the field. This dwarfism was noted by Dutch growers in the seventeenth century and manipulated through careful selection to produce a variety of so-called bush types. Holland Capucijners with two-foot vines, and the delicious raisin Capucijners (which actually do look like dried raisins) represent a further evolution of this old category of pea. While they are technically field peas, these bush varieties were also adapted to kitchen gardens and therefore moved up a notch in culinary status. This brings us to the true gar-

den pea, which is genetically different from its cousins in the field.

The garden pea is written botanically as *Pisum sativum*, spp. *sativum* and is readily recognized by its white flowers. The white flower suggests albinism, especially since the flowers of wild peas are not naturally white. Genetic mutation is further supported by the fact that the seeds are generally very light in color, from near-white to yellow, and when dry are either smooth or wrinkled. Horticulturists now group garden peas by these seed textures since the two types yield peas with different culinary characteristics. Both types, however, contain more sugar than field peas when green, and it was this unusual sweetness that probably first caught the attention of observant gardeners in the Mediterranean some two thousand years ago.

The common white flowering garden pea was known to the ancient Greeks and Romans, but its precise place of origin and date of appearance is unknown. It appears to have been treated as an aristocratic vegetable, hence its mention by Apicius and other classical authors. It was raised in the gardens of the great Roman estates for the luxury of the nobility, but it was not food for the masses: field peas were their sustenance. Garden peas continued to be grown during the Middle Ages, again as food for the aristocracy and church princes. It is not until the horticultural revolution of the 1600s that we find this pea moving into middle-class gardens. The Dutch took the lead in developing new varieties like the tender mange-touts (snap or sugar peas) and the dwarf *petit pois*, but it was the French court of Louis XIV that made green peas fashionable. During the reign of William and Mary, Dutch horticultural enthusiasm caught on in England, and England has remained the center of pea development ever since.

The English have developed elaborate horticultural categories for classifying peas, but doubtless their marrowfats stand out as a singular contribution to this class of vegetable. Marrowfats are peas that are sweet and buttery when cooked green, although they are rarely sold that way in England. Their dry seeds are somewhat chalky in appearance and reduce to a creamy texture when used in soups. Most commonly they are canned, and as a canned product, they became a standard feature of English cookery by the late Victorian period. The very best varieties were developed by Thomas Andrew Knight (1759–1838), a genteel horticulturist who was responsible for a wide range of improved fruits and vegetables. Many of Knight's peas were used by later breeders like Thomas Laxton and Alan MacLean to create some of the Victorian varieties that are still popular today, among them Laxton's Fillbasket (1872) and MacLean's Paradise Marrow (also known as Champion of Paris) introduced in the 1850s.

On the other side of the English Channel, the Paris seed house of Vilmorin introduced some of the most popular pea varieties in nineteenth-century Europe, espe-

### PEAS THE FRENCH WAY

Shell your Peas, and pass a quarter of a Pound of Butter, gold Colour, with a Spoonful of Flour; then put in a Quart of Peas, four Onions cut small, and two Cabbages cut as small as the Onions; then put in half a Pint of Gravy, season with Pepper, Salt, and Cloves. Stove this well an Hour, then put in half a Spoonful of fine Sugar, and fry some Artichokes to lay round the Side of the Dish; serve it with a forced Lettuce in the Middle.

SOURCE: *Adam's Luxury, and Eve's Cookery* (London, 1744).

cially several French varieties that are now much sought after by Paris chefs. These would include Gloire de Quimper, a dwarf bush pea of the *petit pois* type similar to American Wonder, the scimitar-podded Serpette d'Auvergne from the 1830s, and the Pois Géant sans Parchemin (Giant Sugar Pea), which has bicolor flowers, a tell-tale sign of its field pea ancestry.

Through trade contacts with the Dutch and Portuguese, the Chinese and Japanese were introduced to mangetouts (sugar peas) in the seventeenth century. Since then, they have developed numerous new varieties of tender-podded peas popularly referred to in present-day seed catalogs as snow peas or Chinese peas. The sprouts and young pods are commonly employed in stir-fries and should not be confused with commercial American snap peas. Snap peas are large sweet peas with a crisp, edible pod. This name is somewhat misleading since many peas, like the Sickle Pea of the eighteenth century, can be eaten whole like a snap pea when picked very young. Snap peas are really nothing more than an improvement of the old melting marrows or melting sugar peas, as they were called in the 1800s.

Many of the more recently developed varieties, like the Slim Pea, or the odd Parsley Pea with its bushy tendrils, have evolved to reflect very specific shifts in contemporary diet. In the case of the Slim Pea, it makes an ideal freezing pea for small gardens owing to its diminutive vines, not to mention that the name implies weight loss and low calories (peas are very high in calories). Peas were among the first vegetables marketed as frozen food in the 1920s, and today there is increasing commercial interest in varieties that can be frozen and then cooked in the microwave oven. The Parsley Pea represents a much different mentality, since it is a pea that appeals to organic gardeners and followers of macrobiotic or vegetarian diets. Its peas and pods are edible and its tendrils may be cooked and transformed into faux seaweed salad for a meal with the ascetic appointments of Taoist simplicity.

**PEPPER.** For *pepper (spice)*, see **Herbs and Spices**; for *peppers*, see **Chili Peppers**.

**PESTICIDES.** A pesticide is any agent used to kill or control a pest. Pests include insects, weeds, and diseases, such as fungi. In addition, mice, rats, birds, and algae may become pests at some time. When pests damage plants or property, people often use pesticides to control them. The term “pesticide” can apply to insecticides, herbicides, fungicides, antimicrobials, growth regulators, defoliants, and desiccants, most of which are applied to food or food plants before or after harvest. Common pesticides are encountered every day—in pet flea collars, kitchen disinfectants, cockroach baits, swimming pool chemicals, and mosquito repellents. Pesticide products contain both active and inert ingredients, and both must be specified on the label.

#### Pesticide Controversy

Modern farmers use pesticides to help them to grow almost all of the world's food. In general, pesticides have been a quick, effective, and inexpensive method of control for pests that attack most of the world's food crops. Pesticides are credited with helping to save millions of lives by controlling diseases, such as malaria and yellow fever, which are spread by insects. However, most pesticides present some risk of harm to humans, animals, or the environment because they are designed to kill living organisms.

Sulfur, herbal extracts, tobacco, soaps, oil, arsenic, pyrethrum, and lime have been used as pesticides for many centuries, but the widespread use of synthetic pesticides is a relatively recent phenomenon. Dichlorodiphenyltrichloroethane, or DDT, is probably the best known early pesticide. DDT was created in 1873, but it

was not until the late 1930s that Swiss researcher Paul Müller discovered that the compound was effective in killing insects. Müller won the Nobel Prize in Physiology and Medicine in 1948 for his work. DDT was an inexpensive and effective solution to many insect problems, and it virtually eliminated malaria from parts of the world. After World War II, DDT became a common agricultural pesticide. In the 1950s, the United States was producing 220 million pounds of DDT per year.

Insect resistance to the substance developed quickly. DDT residues were found in human milk and fatty tissues, and in wildlife food chains. In 1962 writer and ecologist Rachel Carson wrote *Silent Spring* to warn the public about the long-term effects of misusing pesticides. Carson challenged the practices of agricultural scientists and the government, and called for a change in the way humankind viewed the natural world. Carson testified before Congress in 1963, calling for new policies to protect human health and the environment. While no longer used in the United States, DDT use continues in other parts of the world. Many tropical countries still use DDT to control malaria.

All pesticides (natural and synthetic) have the potential to cause harm during their manufacture or refinement, at the time of application to crops, as residues that persist on food, and in the disruption of the natural balance that exists between pests and their natural enemies. For example, traces of the natural insecticide “rotenone” may be found on vegetables after cooking. Atrazine, a weed-killer commonly used on corn and soybeans, suburban lawns, and utility rights-of-way, has contaminated groundwater where those crops are grown. Insecticides like DDE and dieldrin, which are related to DDT, were banned in the United States in the 1970s, but still show up in the U.S. food supply. Persistent residues of these chemicals travel long distances in global air and water currents. These insecticides are still produced and used in many countries. Recent studies have linked pesticides with acute poisonings, cancer, brain damage, reproductive harm, and many childhood illnesses and learning problems, leading concerned citizens to feel that pesticides should be banned.

#### Organic Agriculture

Some agricultural experts predict that the quality and quantity of our food supply would be lessened if pesticides were eliminated. However, practitioners of organic agriculture (organic farmers use no synthetic agricultural chemicals and instead rely on management practices such as crop rotation, disease-resistant varieties, and natural enemies to control crop pests) claim that food quality and yield are equally productive under organic management. Fortunately for conventional and organic farmers, the number of safer, reduced-risk options for pest control is increasing. For example, there were approximately seven hundred new, biological pesticide products registered by 1999. Biological pesticides are certain types of pesticides

derived from such natural materials as animals, plants, bacteria, and minerals.

Garlic, mint, and baking soda all have pesticide-like properties and are considered biological pesticides. Biological pesticides include the common cabbage worm killer *Bacillus thuringiensis*, which produces a protein that helps to kill specific worm pests. Some of the new reduced-risk pesticides, while synthesized in a laboratory, are considered safer because they do not kill beneficial insects (such as lady beetles and lacewings), or they break down quickly to inactive products. In 1977 U.S. president Jimmy Carter issued a Presidential Decree that mandated the use of integrated pest management (IPM)—a comprehensive approach to pest control that uses a combination of less toxic means to reduce the status of pests to tolerant levels, while maintaining a quality environment. Together, the new reduced-risk pesticides and IPM practices have helped to lessen the amount of pesticides that are used on food and other crops. Levels of pesticide residues on IPM produce have been reported as higher than those of organically grown food, but lower than those in conventionally grown produce.

### Pesticides and Their Regulation

In the United States, pesticides are regulated by the Environmental Protection Agency (EPA). EPA regulates the sale, distribution, and use of pesticides and has the authority to suspend or cancel the registration of a pesticide if information shows that continued use would pose unreasonable risks. In 1996 the Food Quality Protection Act (FQPA) was signed into law, giving EPA more effective power. Among its many benefits, the FQPA established a new health-based safety standard for pesticide residues in food; included special provisions for infants and children; required periodic tolerance reevaluations; incorporated provisions for endocrine testing; and allowed for enhanced enforcement of pesticide residue standards.

Scientists predict that, in the future, pesticides will continue to play a role in pest management of food crops, partly because reduced-risk pesticides have become less harmful to the environment, and less toxic to people and wildlife. Societal concerns, scientific advances, and regulatory pressures continue to drive some of the more hazardous pesticides from the marketplace. In addition, consumer interest in safe and healthy food will create more demand for organically grown products.

**PETRONIUS.** In the surviving manuscript, the authorship of the Latin picaresque novel *Satyrica* is credited to "Petronius Arbiter." Most scholars believe (although conclusive evidence is lacking) that this is Gaius (or Titus) Petronius, who served the Roman emperor Nero as *Arbiter Elegantiae* (judge of elegance, or director of entertainment). He fell from the emperor's favor and was ordered to commit suicide in A.D. 66. The historian Tacitus describes the courtier's death in his *Annals* (book 18, sections 18–19).

The *Satyrica* is a novel of low life in Roman Italy, centering on the narrator Encolpius and his boyfriend Giton. The author may seem to celebrate—he certainly does not condemn—his characters' amoral lifestyle: they are usually penniless and often involved in disreputable sexual adventures.

In medieval Europe the *Satyrica* was a secret classic. No complete copy survived to modern times; we have only fragments. The longest surviving episode (sections

26–78), important for food history, is known as *Cena Trimalchionis*, or ‘Trimalchio’s dinner’. This immensely rich former slave regales his guests (including Encolpius) with food and conversation intended to display urbanity but more truly betraying empty pretentiousness. The main course is a roast pig, served as if still whole. In fact it had been gutted normally, and afterward stuffed with cooked sausages, which look like (and are made from) intestines: a clever, but tasteless, presentational trick. The wine is labeled “opimian, one hundred years old,” but at the date of the fictional dinner any surviving Italian wines of the famous opimian vintage were 180 years old and almost undrinkable: such contradictions are meant to reveal the host’s ignorance of gastronomy. Almost every item in the menu has some satirical undertone. Cleverly balancing between naive astonishment and cynical disdain, the narrator tells us a lot about gastronomy and dining customs under the early empire. Featured among the hors d’oeuvres at Trimalchio’s dinner, dormice (roasted, dipped in honey and rolled in poppy seeds) will forever remain typical of Roman cuisine.

**PHOSPHORUS AND CALCIUM.** Phosphorus and calcium are essential macronutrients in the human diet. Most of the phosphorus in the human body is found in association with calcium (as the mineral complex hydroxyapatite) in bones and teeth, where it is essential to structure. This form of phosphorus, along with phosphorylated sugars and proteins, is termed *inorganic phosphorus*. Organic phosphorus occurs primarily in the form of phospholipids.

Phosphorus absorption in the human body is proportional to the dietary intake, unlike calcium, where absorption is inversely related to the logarithm of intake. Absorption of phosphorus is facilitated by vitamin D. Phosphorus levels in urine are also directly related to dietary intake.

Important regulatory functions of phosphorus in the human body include maintaining the pH of body fluids,

**TABLE 1**

the cellular osmotic pressure, and the energy transfer system in cells. Phosphorus is also an important component of DNA and RNA. Phosphorus deficiencies are rare and have been linked to anorexia, rickets, and skeletal and muscular abnormalities.

The amount of calcium consumed is not always related to the amount retained by the body. Availability of calcium for absorption is referred to as bioavailability, and is improved by factors such as the presence of phosphorus, vitamin D, and the extent to which the calcium mineral salt is ionized to form the divalent  $\text{Ca}^{2+}$  ion. Cellulose and hemicellulose fibers decrease absorption of calcium in the intestine. Sodium and caffeine both increase urinary calcium. Caffeine also causes an increase of calcium secretion into the human gut. Unabsorbed fats interfere with calcium absorption by forming a fatty acid-calcium soap complex, which is subsequently excreted. The bioavailability of calcium ranges from 5 to 70 percent for most foods, depending upon the type of mineral from which it is derived, the food product, and the presence of inhibitory substances. Oxalate and phytate both inhibit calcium absorption. A diet deficient in calcium may increase the risk of rickets, hypertension, osteoporosis, and scurvy. Vitamin D stimulates the absorption of calcium and phosphorus into bones. Osteoporosis is one consequence of low calcium intake during the younger years of bone mineralization. There are conflicting opinions on the efficacy of increasing the intake of calcium for older people who are already suffering from osteoporosis.

About 1.5 percent of the weight of an average person is made up of bones, which contain 99 percent of the body's calcium. Approximately 0.05 percent of the calcium in bones is exchanged daily by a process of solubilization and precipitation. In addition to its structural function, calcium in its ionized form allows blood clotting to take place. Calcium also regulates muscle contraction and relaxation.

Calcium is often found in association with phosphorus, forming the mineral calcium phosphate. This mineral is less soluble at higher temperatures (unlike most other minerals), resulting in "boiler-scale," a white precipitate on surfaces that come into contact with hot mineralized water. Table 1 presents a selection of foods containing phosphorus and calcium and gives the ratio of calcium to phosphorus in each; this is one important indicator of bioavailability. A low calcium to phosphorus ratio is associated with bone loss over time.

Milk is a very good source of dietary calcium. Calcium in milk is found primarily in the mineral calcium phosphate, which is approximately 30 percent bioavailable. It is possible that the high level of insoluble calcium phosphate in milk could cause calcification of the mammary gland, but casein milk proteins solubilize the mineral calcium phosphate. Calcium phosphate and proteins are responsible for much of the high buffering capacity

of milk, which is a resistance to change in pH after the addition of acid or base. This allows milk to absorb a large amount of acid, such as that found in the human gut, providing some relief from acid reflux. Milk also contains a large amount of lactose. This precludes the use of milk as a source of dietary calcium and phosphorus for people suffering from lactose intolerance, an inability to metabolize lactose. For these people, other dairy products such as matured cheese and yogurt can be used to provide dietary calcium. Both of these dairy products are low in lactose. More information on calcium phosphate and lactose in milk can be found in Table 1 under Dairy Products.

Calcium is used in food to increase the gel formation of polysaccharides such as alginate and pectin, which can be used to increase the firmness of canned vegetables. Calcium also increases the firmness of milk gels and the rate of milk clotting, such as what occurs in cheese manufacture, by promoting aggregation of casein milk proteins. Phosphorus is present in emulsifiers used to produce the smooth texture required for processed cheese. It is also used to increase moisture retention in comminuted meats, as a leavening agent, as a pH buffering agent, and to acidify beverages. Phosphorus-containing agents such as phytate, oxalate, and phosphate act as chelating agents by binding calcium strongly.

The recommended dietary allowance for calcium is 210 mg/day (from birth to six months), 270 mg/day (aged seven to twelve months), 500 mg/day (aged one to three years), 800 mg/day (aged four to eight years), 1,300 mg/day (aged nine to eighteen years) and 1000 mg/day above eighteen years of age. The recommended dietary allowance for phosphorus is 100 mg/day (from birth to six months), 275 mg/day (aged seven to twelve months), 460 mg/day (aged one to three years), 500 mg/day (aged four to eight years), 1,250 mg/day (aged nine to eighteen years) and 700 mg/day above eighteen years of age.

#### PHYSICAL ACTIVITY AND NUTRITION.

Regular physical activity and proper nutrition are critical for optimal health. Both have been linked to reducing the risk of a large number of common chronic diseases. In most cases, it is difficult to separate the roles

## BENEFITS OF REGULAR PHYSICAL ACTIVITY

- Decreases the risk of premature death
- Decreases the risk of dying prematurely from coronary heart disease
- Decreases the risk of Type II diabetes mellitus
- Decreases the risk of hypertension
- Helps reduce blood pressure in people with hypertension
- Decreases the risk of colon cancer
- Decreases feelings of depression and anxiety
- Helps control body weight
- Helps build and maintain healthy bones, muscles, and joints
- Improves strength in older adults and decreases their risk of falling
- Promotes psychological well-being

these two factors play in decreasing disease risk. The importance of both of these factors is highlighted by the United States government in the *2000 Dietary Guidelines for Americans* published by the U.S. Department of

Health and Human Services and the U.S. Department of Agriculture. The guidelines' recommendations include aiming for a healthy weight; being physically active each day; following the food guide pyramid; eating a variety of grains, fruits, and vegetables each day; choosing a diet low in saturated fat and cholesterol and moderate in total fat; consuming less sugar and salt; drinking alcohol only in moderation, if at all; and keeping food safe to eat. These suggestions can greatly reduce disease risk. The role of physical activity in particular is a primary focus in the article that follows.

## Benefits of Physical Activity

The 1996 Surgeon General's report, *Physical Activity and Health*, summarized many of the advantages obtained through participation in regular physical activity. It should be noted that these benefits can be acquired through a broad variety of activities; thus, the terms "exercise" and "physical activity" should not be limited solely to describing activities that are specifically designed to enhance fitness. Activities considered beneficial to health include structured exercise (e.g., walking, running, cycling, weight lifting, etc.), participation in sports, leisure-time and recreational pursuits, occupational duties, and other forms of movement.

Jeremy Morris and colleagues (1953) were among the earliest researchers to suggest that physical activity confers benefits to health. In their study, the rate of coro-

Physical activity and a balanced diet are underlying themes in modern food advertising. This breakfast cereal uses golfing hero Tiger Woods to draw a connection between the food product and winning a sport. It could be argued that the easy pace of golf should not be equated with a full physical workout. © AP/WIDE WORLD PHOTOS.

## AMERICAN COLLEGE OF SPORTS MEDICINE GUIDELINES FOR FITNESS

### ***Cardiorespiratory Fitness and Body Composition***

1. Frequency of training: 3–5 days per week.
2. Intensity of training: 55/65 percent–90 percent of maximum heart rate. The lower intensity values (55–65 percent) are most applicable to individuals who are quite unfit.
3. Duration of training: 20–60 minutes of continuous or intermittent (minimum of 10-minute bouts accumulated throughout the day) aerobic activity. Duration is dependent on the intensity of the activity; thus, lower-intensity activity should be conducted over a longer period of time (30 minutes or more), and, conversely, individuals training at higher levels of intensity should train at least 20 minutes or longer.
4. Mode of activity: Any activity that uses large muscle groups, that can be maintained continuously, and that is rhythmic and aerobic in nature, e.g., walking-hiking, running-jogging, cycling-bicycling, cross-country skiing, aerobic dance or group exercise, rope skipping, rowing, stair climbing, swimming, skating, and various endurance game activities or some combination thereof.

### ***Muscular Strength and Endurance, Body Composition, and Flexibility***

1. Resistance training: Resistance training should be an integral part of an adult fitness program and should be of a sufficient intensity to enhance strength and muscular endurance, and to maintain fat-free mass. Resistance training should be progressive in nature and individualized, and should provide a stimulus to all the major muscle groups. One set of 8–10 exercises that conditions the major muscle groups 2–3 days per week is recommended. Multiple-set regimens may provide greater benefits if time allows. Most persons should complete 8–12 repetitions of each exercise; however, for older and more frail persons (approximately 50 to 60 years of age and above), 10–15 repetitions may be more appropriate.
2. Flexibility training: Flexibility exercises should be incorporated into the overall fitness program sufficient to develop and maintain range of motion. These exercises should stretch the major muscle groups and be performed a minimum of 2–3 days per week.

nary events (i.e., angina pectoris, thrombosis, death) for double-decker bus and tram conductors in London was compared to that of their more sedentary driving counterparts. Conductors had an overall lower incidence of coronary events and mortality than drivers, and the authors suggested that the greater level of physical activity that results from conducting versus driving might be the explanation. Many other investigators have since confirmed the notion that being more active reduces risk of heart disease and premature death, as well as many other common health problems.

Many of the health benefits of exercise are probably indirect, through control of body weight; however, physical activity alone also appears to be helpful. A recent review of the literature by Stephen Blair and Suzanne Brodney (1999) concluded that the current understanding of the importance of exercise to health suggests that physical activity reduces health risks that are usually associated with overweight and obesity, even in those who remain obese. Furthermore, they concluded that inactivity and low cardiorespiratory fitness increase the risk of premature death so that the risk is equal to being overweight or obese. Thus, physical activity is essential for optimal health regardless of body weight.

The reasons for the apparent health benefits of physical activity with regard to multiple disease conditions

have been addressed by many studies. Although all of the mechanisms are not yet completely understood, several physiological effects of exercise have been observed and may be responsible. It is likely that improved cardiac and musculoskeletal function account for many of the benefits. Additionally, physical activity alters metabolic and hormonal processes that may modify disease risk, and activity also appears to be involved in improving immune function.

### **Physical Activity Guidelines**

Quantifying the optimal level of physical activity required to reduce the risk of disease has proven difficult. However, leading organizations have provided recommendations for minimal levels of activity. Exercise guidelines from the American College of Sports Medicine (1998) for cardiorespiratory fitness, muscular strength and endurance, flexibility, and body composition are provided in the sidebar “American College Sports Medicine Guidelines for Fitness.” Additionally, the Surgeon General’s report (1996) recommends that people of all ages include a minimum of thirty minutes of physical activity of moderate intensity (such as brisk walking) on most, if not all, days of the week. Furthermore, two objectives of Healthy People 2010 (2000), a set of health objectives developed by the United States Department of Health and

Human Services, are, first, to increase the proportion of adolescents who engage in vigorous physical activity that promotes cardiorespiratory fitness three or more days per week for twenty or more minutes per occasion, and, second, to increase the proportion of adults who engage regularly, preferably daily, in moderate physical activity for at least thirty minutes per day.

Although numerous positive effects of physical activity exist, participation in strenuous exercise and work is not completely without risk in all circumstances. Primary risks include musculoskeletal injuries and cardiovascular events such as heart attacks. To avoid musculoskeletal injuries, it is most commonly recommended when beginning a physical activity program that the participant gradually increase the duration and intensity of the routine. Although physical exertion can result in a cardiovascular event, this is a rare occurrence in the healthy population. However, the Surgeon General's report (1996) suggests that adults with chronic diseases, such as heart disease, diabetes, or obesity, consult a physician before starting a program of physical activity, as should men over forty years of age and women over fifty years of age who plan to start a "vigorous" exercise program.

## Conclusions

Many beneficial effects of diet and exercise are known; however, the interactive effects of the two are less understood. The relative importance of these lifestyle choices on various risk factors for chronic diseases is not clear. In some cases, physical activity and proper nutrition effects may be additive. In other cases, a synergistic effect of the two may exist. Additionally, it is also possible that for some risk factors, high levels of physical activity may even negate the adverse effects that a poor diet typically has on more sedentary individuals. For example, regular strenuous exercise appears to abolish the cholesterol-raising effects of a diet high in saturated fat. Clearly, the interaction between physical activity and nutrition relative to health benefits deserves considerable investigation now and in the future, so that we may optimally manage risk for chronic diseases.

**PICA.** See **Geophagy**.

**PICNIC.** There is no reliable etymology for the word *picnic*, with the original use of the word lagging about three hundred years behind the first descriptions of *alfresco* (open air) dining. From about 1340 until the very early 1800s, there are three contextual descriptions of picnics, whether or not the word is actually used: a pleasure party at which a meal was eaten outdoors; a hunt assembly; and an indoor social gathering or dinner party. An outdoor meal in a garden is described in Italian literature by Giovanni Boccaccio in a poem that dates from about 1340. Sixty years later a similar event occurs in one of Geoffrey Chaucer's *Canterbury Tales*. It seems certain that the *assemblée*, or meal served during the hunt that is described and illustrated in the hunt manual of Jacques du Fouilloux's *La Vénerie* (Hunting) (1560) and George Turberville's *The Noble Arte of Venerie* (1575), are picnics in all but name. By 1692, the concept of the *alfresco* meal shifted, and when cited in Gilles Ménage's *Dictionnaire de l'Etymologique de la Langue Française* (Etymological dictionary of the French language) *pique-nique* is assumed to be of unknown origin, but means *un repas où chacun paye son écot* (a meal where each pays his share). By 1750, Ménage's editors suggest that *pique-nique* may be of Spanish origin and that it appeared in 1664 in a French translation of works by Francisco Quevedo. Oliver Cromwell, Lord Protector of Great Britain, had a dinner served on the grounds of Hyde Park in 1654. Samuel Pepys, the English diarist, ate many meals while boating on the Thames or sitting on its banks. These are picnics in all but name, but they are only recorded as a dinner *alfresco*.

The *Oxford English Dictionary* says that the word "picnic" originally referred to fashionable social entertainment in which each person contributed a share of the provisions, and says that the first recorded use of "picnic" in English appears in 1748 in a letter from Lord Chesterfield to his son, in the sense of an assembly or social gathering. It seems that the word was used in this sense widely in Germany, as Chesterfield's son was in Berlin at the time. A subsequent mention occurs in a letter from Lady M. Coke to Lady Stafford in 1763 from Hanover. Gustaf Palmfelt, a Swede, in a 1738 translation into Swedish used "picnick" (in the sense of an assem-

## AN EGYPTIAN PICNIC

Claudia Roden's "A Middle Eastern Affair" in *Everything Tastes Better Outdoors* (1985) tells that her favorite picnic spot was in the dunes of Agami in Alexandria, where she was raised as a child. She explains that in the Middle East eating out is a way of life: "There are even official occasions for picnic. Among these are the *mulids*, when people flock to the principal scenes of religious festivals, public gardens, shrines, tombs of saints, and burial grounds. Thousands gather sometimes for days and nights, sleeping under tents . . . The most important of the national picnics in Egypt is not a religious occasion. It is *Shem en Nessem*, which celebrates the arrival of spring. Town dwellers go out in the country or in boats, generally northward, eating out in fields or on the riverbank, smelling the air, which is thought to be particularly beneficial on the day" (pp. 167–168). Picnic foods include *blehat samak* (Fish rissoles), *qras samak* (Arab fish cake with burghul,) brains Moroccan style, *sambusak* (pies filled with meat and pine nuts), meat *ajja* (an omelet) *kukye gusht* (an Iranian omelet) *kibbeh naye* (raw lamb and cracked wheat paste), *bazargan* (burghul salad), *tabbouleh* (cracked wheat salad), stuffed vegetables, stuffed onion, leeks, zucchini, lemon chicken, *lahma bil karaz* (meatballs with cherries), *salq bi loubia* (spinach with black-eyed beans), lentil tomato salad, and *loubia bi zeit* (green beans in olive oil).

pp. 152–153). Mrs. Isabella Beeton's recommendations for a picnic for forty persons are for formal entertaining carried outdoors in some location where an elaborate feast could be organized and served by servants.

Elizabeth David, a known lover of picnics, says that

Picnic addicts seem to be roughly divided between those who frankly make elaborate preparations and leave nothing to chance, and those others whose organization is no less complicated but who are more deceitful and pretend that everything will be obtained on the spot and cooked over a woodcutter's fire conveniently at hand (*Summer Cooking*, p. 208).

James Beard suggests that a picnic requires that you travel somewhere to eat. He is certain that

Wherever it is done, picnicking can be one of the supreme pleasures of outdoor life. At its most elegant, it calls for the accompaniment of the best linens and crystal and china; at its simplest it needs only a bottle of wine and items purchased from the local delicatessen as one passes through town. I recall a recent

bly); Swedish continues to use "picnick" and suggests that it is of French or English origin. *Larousse Gastronomique* (2002) states that 'picnic' is a contraction of *pique* (to pick), *piquante* (sharp or pungent), and *nique* (of small value). This suggestion seems commonsensical, but it is guesswork based on the technique of word formation by clipping words together to form a new word.

In the arts and literature, picnics tend to be more concerned with place, action, and figurative meanings and less concerned with food, if it is mentioned at all. Oliver Goldsmith, whom Georgina Battiscombe (*English Picnics*, 1949) credits with describing the first picnic in English literature in *The Vicar of Wakefield* (1766) provides these bare bones: "Our family dined in the field, and we sat, or rather, reclined round a temperate repast, our cloth spread upon the hay." Battiscombe insists that a picnic must be a meal eaten outdoors to which diners bring something to eat, even if there is no sharing. She suggests that before the Romantics made nature fashionable "no one connected the idea of pleasure with the notion of a meal eaten anywhere but under a roof" (p. 4).

In London, the so-called Picnic Society (1802) was a short-lived elite social club organized for entertainment. But a decade later "picnic" is used only in the sense of a meal eaten outdoors. Occasionally, it was used in the sense of an anthology, as in Charles Dickens's *The Pic-Nic Papers, by Various Hands* (1841), or as a term of disapprobation as in a person accused of picnicking and nicknackery, or being frivolous.

Germans use *picnick* in the sense of holding a meeting, as in the phrase *ein Picknick halten*. The verb is *picknicken*, which literally means holding a picnic as you would hold a meeting or a party. Italians use *scampagnata* (holiday in the country), or *lolazione sull'erba* (luncheon on the grass). Spaniards use *comida al aire libre* (luncheon on the grass), or *comida campestre* (eat in the country). Spanish dictionaries seem unaware that Ménage thinks the word may be of Spanish origin. Koreans use both the Chinese *so pong* (a little meal in the country) and "picnic." Their favorite picnic time occurs when the cherry trees are in bloom. The Japanese have a long history of depicting meals taken outdoors, often celebrating *hanami*, the cherry blossom season, or another seasonal event. In 1862, "picnic" was translated as *shokuji* (meal), and in the twentieth century, the Japanese adopted the loanword *pikunikku*.

### Food Writers on Picnics

Cookbooks are excellent resources for picnic menus and recollections. Jean Anthelme Brillat-Savarin delights in the hunt assembly ("Halts of a Shooting-Party"), which he does not call a picnic: "At the appointed hour we see arrive light carriages and prancing horses, loaded with the fair, all feathers and flowers. . . . Seated on the green turf they eat, the corks fly; they gossip, laugh, and are merry in perfect freedom, for the universe is their drawing-room, and the sun their lamp" (*Physiologie du goût*,

Grapes are one of the oldest and most universally popular picnic fruits, and no tasteful American picnic is complete without wine and cheese—or the ever-popular cold fried chicken.

© ARTHUR ROTHSTEIN/CORBIS.

picnic in France where we bought *rillettes de Tours* (in Tours), and elsewhere some excellent *salade museau*, good bread, ripe tomatoes and cheese. A bottle of local wine and glasses and plates from the Monoprix helped to make this picnic in a heather field near Le Mans a particularly memorable one (*Menus for Entertaining*, p. 272).

Claudia Roden, aficionado of picnics and outdoor eating, describes English picnics, Revival Week picnics, a Middle Eastern Affair, a Japanese Picnic, and a Picnic in the Himalayas. Roden confesses,

The pleasures of outdoor food are those that nature has to offer, as ephemeral as they are intense. A bird will sing his song and fly away, leaves will flutter and jostle the sunlight for a brief second—sky, flowers, and scents have each their small parts to play in the perfect happiness of those enchanted moments. They serve, as Jean Jacques Rousseau said, to “liberate the soul” (*Everything Tastes Better Outdoors*, p. 4).

**PIE.** The word *pie* derives from a related word *piece*, as expressed in medieval Latin *petia* or *pecia*. Both terms can be traced to Gaulish *peth* (Lambert 1997), which appears as *pighe* in Irish and Scottish. The core meaning of the word both in Celtic and in later medieval Latin was twofold: a morsel which could be eaten with the fingers and which also contained some type of filling—in short, a pastry envelope.

#### Pocket Pies

The Gaulish origin of our English word does not imply that the Celts invented the pie concept; it merely underscores the fact that this culinary idea is one of great age and wide distribution, with many counterparts in the Near East and Asia. It also reaffirms the growing realization among food historians that many modern concepts, such as *bouillon-blanc* (early medieval *bugillo albo*) derive from non-Roman European cultures, although they are transmitted to us through Medieval Latin.

In keeping with this, the original “pie” at least as it was known to continental Celts, consisted of a square, triangular, or more commonly a circular piece of dough folded over a filling and pressed together to form a half-moon or pocket. This concept was carried over into medieval cookery, and linguistic evidence suggests that these pies were large, since diminutive adjectives or endings were needed to describe small ones. In medieval everyday cookery such pies probably served as a substitute for roast meat since they could employ meat leftovers or such for-

aged poverty fillings as elderberries or sorrel. Furthermore, they could be baked down hearth in a kettle set on a tripod over hot coals, with some of the coals scattered over the kettle lid. The ease with which such fare could be prepared in very simple medieval kitchens may explain why the pie became so firmly integrated into the traditional cookery of the British Isles. However, in medieval court cookery, handheld pies formed an adjunct to other dishes brought to the table, and very often contained exotic ingredients or flavors intended to contrast with carefully orchestrated sauces, dips, and roasted meats.

The identifying pocket shape, which is highly convenient in societies where food is eaten with the fingers, may be found in many traditional grain-based cookeries where flour is compounded with oils or fats in a variety of ways. This age-old concept survives in the form of Spanish *empanadas*, in English turnovers, in Greek *kolokotes*, and in a vast number of other similarly shaped foods now prepared in both the Old and New worlds—even in the modern pop tart invented for toasters.

One thread common to all forms of traditional pocket pies is that the crust was usually short (with a high fat content). Because of this, the pie was normally associated with festive or special occasion cookery, and thus forbidden by the Christian church for consumption on lean days or on days of fasting. This restriction varied regionally since ecclesiastical enforcement was at best uneven.

Restrictions were profoundly altered during the Protestant Reformation, which did away with fast days. Thus the pie became a status symbol, which in time assumed far more importance in English cookery than it did on the Continent. This cultural emphasis was transferred to North America through English colonization. Furthermore, by the time the pie reached American shores in the seventeenth century, it had already undergone several transformations in England, so that there was not one, but five types of pastry called pie: pocket pies, two-crust pies, one-crust pies, standing pies, and potpies. All these forms evolved distinctive English identities during the late Middle Ages and were slow to change, since they became tied up with concepts of English national identity.

Even into the nineteenth century, the pocket pie in its most ancient meaning lingered on alongside the newer forms in both demotic speech and literature, especially in cookery books of a highly colloquial nature. The unifying principle was that they were considered finger food during a period of English cookery predating the introduction of forks—quite literally something broken or cut into pieces. Indeed, this idea of eating with the hands has persisted for a very long time and is still preserved in such American creations as the Pennsylvania Dutch shoofly pie, a breakfast cake baked in a pie shell and meant to be sliced, held in the hand, and dipped into strong coffee.

This marriage of very different types of pies under the umbrella of one term is further linguistic evidence that the turnover shape was indeed the oldest type and

## DRIED PUMPKIN PIE

In the age before canned pumpkin puree, home cooks had only two choices: fresh pumpkin from the winter pantry, or dried pumpkin. The internal reference to a brick bakeoven suggests that the setting for the following recipe is a well-off farm somewhere in the Middle States, where bread baking was still done in an outdoor bake house.—Ed.

Dry the pumpkin after the following manner: — Boil it a good while, then spread it upon plates, or drop a spoonful at a time upon buttered paper, which is laid on tins, forming cakes, as it were, and set the tins into a brick oven after you have removed your baking; it dries in this way, without getting dusty.

In making the pies, take for one pie three cakes of pumpkin, and three eggs; sugar to your taste; soften the pumpkin in warm milk; strain through a colander; spice with cinnamon, and bake in a deep dish. This is an excellent pie, and preferred by some persons to the fresh pumpkin.

When well dried, the pumpkin will keep more than a year.

SOURCE: *Breakfast, Dinner, and Tea* (New York, 1883), p. 176.

that the English language did not have a wide range of indigenous terminologies to accommodate the newer forms. It is also evidence that the transition from one form to the next was sometimes gradual, especially in the countryside. Food historians generally concur that there is a definite genealogical link between the ancient pie and its modern two-crust descendant, although there is no firm agreement as to how this transition took place. There are several possible avenues of evolution. The shallow dish or saucer pie and the deep dish or potpie offer two theoretical possibilities.

### The Saucer Pie

A turnover or large pocket pie that is baked in a saucer-like dish were known colloquially as saucer pies (Coolidge, 1875; Weaver, 1990) and consisted of one, sometimes two, turnovers baked in a small redware saucer and served in it. Milk could be poured over the pie, which was mashed and thus eaten like porridge. The next stage in the evolutionary line is achieved when the pastry dough is spread over the saucer and the dish rim is used for sealing the upper crust. The pie then moves from half-moon or pocket shape to circular. It can still be lifted from the dish and eaten out of hand, but the new shape now requires the use of a knife to cut it.

## MUGGETY PIE

The following is a traditional British pie of a highly regional type made with an unusual sort of mincemeat: sheep's pluck, otherwise known as sheep's heart.—Ed.

Prepare a sheep's pluck by soaking in water and thoroughly cleaning. Boil for several hours, and when cooked, put through mincing machine; then add a few currants, season well, and flavour with parsley or spice. Mix well together, put into a pie dish, cover with good short crust, and bake three-quarters hour.

SOURCE: Edith Martin, *Cornish Recipes* (Truro, England, 1937), 38.

An alternative form, which persisted into the nineteenth century (Leslie, 1857), was the saucer pie with only a thick upper crust. The baked pie was then turned out into a bowl with the top crust down so that it could be broken up and eaten with the fingers or so that milk could be poured over it for eating communally with a spoon. In either case, the underlying concept is one of expansion: the small handheld pie evolves into something of larger size for communal consumption.

### The Potpie

The deep-dish or potpie form evolved parallel to this and appears to have very old antecedents in military and seafaring diets. It was a pragmatic adaptation imposed by limited equipment, in this case the employment of an iron kettle or cauldron over charcoal or over an open fire. The interior of the pot was lined with dough and the pot filled with ingredients including small pieces of dough often referred to as dumplings, then sealed on the top with a pastry lid. The pie was more or less stewed until thick inside its pastry cocoon, rather than baked, but like the one-crust saucer pies, it too was turned out with its pastry parts and eaten communally with a spoon or piece of bread. The fish chowders of the North Sea Celts were prepared in this manner. Early American peach potpie conforms to this premedieval type, although the ingredients give it a thoroughly New World twist. If the potpie is taken one step further and prepared in a shallow dish, it is transformed into the sort of common two-crust pie we know today. This is yet another possible line of evolution.

The potpie was especially popular on the American frontier, and the lore surrounding that historical role is rich. It continues to be a popular one-pot meal with many Americans even to this day, but it has evolved into a type of baked stew served with or without a largely ornamental top crust and has little resemblance to the rustic ancestral form once prepared in a large iron pot.

## Two-Crust Pies

In the context of English cookery, both types of two-crust pies appear to have gained in popularity during the Reformation. They gradually moved from Sunday fare in the eighteenth century, to almost daily fare for farmers during the nineteenth. In both England and America, lard was the universal shortening ingredient for the crust. Butter was only used by the well-to-do. One of the most common types of round, two-crust pie was also the cheapest: pies made with apple fillings, either from fresh apples or from dried apples soaked in hot water or cider. The apple pie was such standard fare in British and American farmhouse cookery that it became a symbol for the cookery as a whole.

### Pies Derived from Tarts

The two other types of pie in Anglo-American cookery derive from quite divergent origins. The first is the shallow pie without top crust (or ornamented with a lattice-work crust). These are often referred to as tarts in old English cookery books, and in fact derive from flat cakes covered with a filling. This category of pie includes fruit tarts and baked puddings, the most famous of the latter being American pumpkin pie (technically a custardlike pudding). It also appears in the blurring of distinctions inherent in such Americanisms as "pizza pie," a linguistic attempt to make a traditional Mediterranean flatbread conform to older Anglo-American notions of pie-like things. The pizza is, after all, cut up into pieces and eaten out of hand.

### The Raised Pie

The fifth type of pie is the raised or standing pie. This type of pie reached its zenith during the Middle Ages, when it served as an *entremet* or showpiece for banquet entertainments. In this case, emphasis was not so much on the taste as on the spectacle it created when brought to table, for there are many well-documented instances where pies were constructed to resemble castles, or built to encase whole roasted animals, or which popped open to reveal musicians, or served as a temporary prison for the four-and-twenty blackbirds mentioned in an old children's rhyme. The crust of such pies was incidental as food, and normally consisted of coarse flour mixed with hot water until it could be molded like clay. It baked hard and was given to the hounds or to the poor.

The game and fish pies of the Victorian era baked in copper or tin molds are lineal descendants of this old culinary tradition. In fact, several English china manufacturers created serving pieces imitating the color and shapes of elaborate game pies. These ceramic substitutes dispensed with the trouble and unpredictability of crusts assembled by poorly trained cooks, and of course they could be used over and over as needed. Like elaborately crusted pies made of real pastry, the expensive china ones also served as the focal point for festive occasions, such as Christmas, a hunt luncheon, or a wedding.

However, the standing pie of greatest importance in English cookery appears to have been mincemeat, and the elaborate construction of the crust was no less important than the spiciness of the filling inside. The Reformation did away with sumptuary restrictions; thus mincemeat could be consumed all through the winter. In fact, it became a fixture in winter cookery both in Britain and America. Diaries from the eighteenth and nineteenth centuries often mention baking large numbers of mincemeat pies for storage in a cold pantry and then consuming them as breakfast, dinner and supper fare. Ground beef, suet, chopped apples, and dried fruit (commonly raisins) formed the core ingredients and doubtless provided high-energy food for hardworking farmers. This common man's mincemeat pie devolved from the elaborate standing crust of a manorial Christmas feast to the sort of old two-crust ed affair tracing its origin back to the pocket pie. Indeed, pocket pies filled with mincemeat also served farmers as snacks in the field, their convenience and practicality ensuring the survival of the form into this century under the dialect name of pasty (also called fried pie), especially in eastern mining towns and in the American upper Midwest. Pasty is also a term used for the leek-and-potato pies of Cornwall in England.

### The Pie as a Styled Centerpiece

There has been a noticeable evolution down through the centuries in the presentation of pies as culinary centerpieces to the formal dessert course. Part of this is due to the ever-changing role the pie has played as a symbol of wellbeing and status. In fact, the treatment of the pie probably mirrors larger shifts in social values about food, indeed even the philosophical aspirations of the beholders.

The medieval standing pie, with its elaborate detail, gilding, and highly artificial appearance doubtless reflected a sense of suppressing nature through art. The choice of ornamental themes definitely appealed to medieval idealism and a fascination with romantic anachronisms—such as the popular tale of the fish-woman Mélusine. This boisterous artificiality is certainly carried down into Renaissance and Baroque cookery, but by the same token, it is obvious from period paintings and prints that pie bakers were also masters of crust design. Even small pies were meant to be studied up close, and therefore they were covered with neat, tight patterns as crisply executed as sculpture. The farmhouse pie was never quite that elaborate, but it was a centerpiece and a measure of the housewife's cooking abilities. So her crusts were no less neat, even if only ornamented with a careful rim and the so-called "bird-track" patterns commonly seen in nineteenth-century prints. This preoccupation with fine detail was important to a world in which everything was made by hand: the more artificial, the more sculpted, the more it stood out as a thing of beauty.

Industrialization changed this attitude dramatically. The craftsmanship of pie baking was replaced by the industrial pie sold frozen in tin pans, the crusts pressed out

### METHODIST MINCEMEAT

Why eat mincemeat? It is a symbol of Christmas luxury, and therefore deeply embedded in religious sensibilities, at least in the English-speaking world. Rather than reject it on grounds of high church decadence, the object of some Protestant groups became to reform it, that is, to bring it in line with their shifting religious values. This reform was undertaken on two fronts, although they overlapped considerably. One was to eliminate alcohol, the other was to abjure the "carnal kitchen"—the consumption of meat. Temperance and vegetarianism come together in the following working-class version of Christmas luxury purified of sin.—Ed.

Yield: one 9-inch pie or 12 tartlets

Short crust

1 large lemon

8 tablespoons unsalted butter

$\frac{1}{2}$  cup brown sugar

$1\frac{1}{2}$  cups dried currants

3 large apples

$\frac{1}{3}$  cup lemon juice

2 teaspoons ground cinnamon

$\frac{1}{4}$  teaspoon ground clove

1 teaspoon freshly grated nutmeg

$\frac{1}{2}$  cup chopped candied citron

Line the pie pan or tartlet pans with short crust. Remove the pithy membranes from the lemon and cut the rind into quarters. Place the rind on a saucepan and cover with boiling water. Simmer 20 to 30 minutes, or until the rind is tender. Strain, reserve the lemon rind, and discard the bitter water. Chop the rind very fine in a food processor.

Preheat the oven to 350°F (210°C). Melt the butter in a deep stewing pan, add the sugar and currants and cover. Stew the currants until they are plumped. Pare, core, and chop the apples, and add them to the currants together with the chopped lemon rind, the lemon juice, and the spices. Cook for 15 minutes, then add the citron and remove from the stove.

When the filling is cool enough to work with, fill the pie shells and cover each with a top crust. Bake in the preheated oven for approximately 25 to 30 minutes; the tartlets will bake in about 20 minutes.

by machine. Therefore, in the early twenty-first century, the rustic look is in. Large, crudely executed patterns, clumsy rims, crusts indeed much too thick for the pies

## CLASSIC LEMON MERINGUE PIE

Recipe of Cecilia Rubio, Perris, California, and 1987 national winner of the Crisco American Pie Celebration contest.

Yield: one 9-inch pie  
one 9-inch pie crust pre-baked and cooled.

Filling:

1½ cups sugar  
¼ cup cornstarch  
3 tablespoons all-purpose flour  
¼ teaspoon salt  
1½ cups hot water  
3 egg yolks, beaten  
2 tablespoons butter or margarine  
1½ teaspoons grated lemon peel  
⅓ cup plus 1 tablespoon fresh lemon juice

Meringue:

½ cup sugar, divided  
1 tablespoon cornstarch  
½ cup cold water  
4 egg whites  
¾ teaspoon vanilla

Preheat the oven to 350°F (210°C). Assemble the filling by combining the sugar, cornstarch, flour, and salt

in a medium saucepan. Add the hot water, stirring constantly. Cook and stir over a medium heat until the mixture comes to a boil and thickens. Reduce the heat to low. Cook and stir constantly for 8 minutes, then remove from the heat. Slowly add about 1/3 of the hot mixture to the egg yolks and mix well. Return this to the saucepan and bring to a boil over a medium heat. Reduce the heat to low and cook 4 minutes, stirring constantly. Remove from the heat and add the butter and lemon peel. Add the lemon juice slowly so that it does not curdle the mixture, then spoon the mixture into the pre-baked pie crust.

To prepare the meringue, combine 2 tablespoons of sugar with the cornstarch and cold water in a small saucepan. Stir until the cornstarch is fully dissolved, then cook and stir over a medium heat until the mixture is clear. Set aside to cool.

Combine the egg whites and vanilla in a large bowl. Beat until soft peaks form, then beat in the remaining sugar, adding it 1 tablespoon at a time. Combine the meringue with the cornstarch mixture and beat until it forms stiff peaks. Spread this over the filling so that it completely covers the pie and seals it at the edges.

Bake in the preheated oven for 12 to 15 minutes or until the meringue becomes golden. Cool to room temperature before serving.

they cover, nonetheless convey the immediate impression that they are handmade and therefore of greater intrinsic value than the commercial article. To the master pie baker of the past, these modern-day creations would appear as though flopped on the table by a child, but it is this very naïveté, this “country look” that modern food journals find so appealing as cover art subjects. That the pie is a perennial showpiece for the covers of magazines and cookbooks speaks volumes about its power as a food symbol.

### The Pie as Symbol: Motherhood and Apple Pie

It is no exaggeration to suggest that the pie is perhaps one of the ultimate icons of American cookery. This idea is not new. In an 1874 issue of the *Household* the editor made this comment:

If we have a national dish . . . we suppose its name is Pie. The line between winter and spring is accurately defined in the minds of half the housewives in the country as the time when there is nothing to make pies of. Dried apples are used up, prunes are too expensive, and rhubarb has not yet made its appearance.

The pie became a symbol of American cookery because of its huge diversity and easy adaptability to

seasonal dietary changes. There are pies for festive occasions: cranberry, mincemeat, and oyster pies for Christmas; pumpkin pies for Thanksgiving. There are pies for life cycle events, such as the funeral pie (otherwise known as raisin pie) among the Pennsylvania Dutch. And there are a great number of pies closely identified with regional cookeries, such as Boston cream pie in New England; pecan, sweet potato, and Key lime pies in the South; tuna pie (made with cactus pears) in the Southwest; and vinegar and molasses pies in the Midwest. Both of the latter pies were also known as harvest pies since they were served to field hands during haying and other harvest periods.

The harvest was one of the most evocative subjects for American art and literature in the preindustrial era, and images of pies are woven into that rich tapestry of food iconography. Industrialization did not destroy the pie's symbolic value, but rather transformed it into new images like pie à la mode (literally “pie in the latest style”), which married a scoop of vanilla ice cream to a slice of pie. This symbol of working class indulgence soon became an icon for diner and soda fountain fare. Likewise, the numerous meringue covered pies, originally referred to by the baking trade as pies in the “hotel style” (a

metaphor for luxury food), achieved their greatest popularity as standard fare at diners and truck stops during the Great Depression. Homemade meringue pies were also featured desserts for church suppers, not to mention worthy material for pie baking contests.

The voluptuousness of a well-made meringue pie was not lost on Hollywood, since the culinary perfection it stood for could be converted into high comedy by means of the outbursts of pie throwing which occur in many old black and white films. We do not see apple pie (a symbol of patriotism) or mincemeat pie (a symbol of Christmas) thrown into peoples' faces. But meringue clinging to the cheeks of a wide-eyed blonde-haired woman elicited laughter, real and perhaps also somewhat nervous, because in the context of those times the image was unquestionably lewd.

**FIG.** Human beings eat more meat of the pig than any other domesticated livestock on earth, even with pig being a food forbidden to more than one billion followers of Islam or Judaism. This lowly beast, whose intelligence and cleanliness has been underestimated for centuries, is a prolific animal that quickly converts a variety of feeds to a mild-flavored meat. One of the first domesticated animals, the pig appears in oriental and Greco-Roman mythology as well as in the Torah, the Bible, and the Qur'an. Despite its utility as a source of food, leather, and pharmaceuticals, the word, pig, is an insult or gentle rebuke in many cultures. While the pig itself may not have grown more controversial, its modern, industrialized husbandry draws criticism from an array of opponents.

### The Omnivorous Pig

The pig, *Sus scrofa domestica*, is a subspecies of *Sus scrofa*, the Eurasian wild boar. It is in the order of mammals, Artiodactyla, which means even-toed and hoofed. That order includes ruminant livestock such as cattle. Bacteria in the rumen help these animals digest cellulose in grasses. *Sus scrofa* is a member of the Family Suidae, or swine. These animals do not ruminate and cannot digest grasses. They are omnivores. In the wild, their diet is fungi, leaves, roots, bulbs, tubers, fruit, snails, earthworms, small vertebrates, eggs, and carrion. The Suidae family includes African bush pigs and African warthogs.

There are some three hundred breeds of domestic pigs. Most are endangered. In the United States, only eight breeds are widely used for commercial production: the Berkshire, Chester White, Hampshire, Duroc, Yorkshire, Landrace, Poland China, and Spots. The Meishan breed, developed in China two thousand years ago, was imported to the United States in 1989 for research and to add genetic diversity.

In common usage, most people make no distinction between a pig and swine, but the precise meaning of pig is "a young swine." The experienced swine breeder Kelly Klobner notes that "what really separates the pros from the tenderfeet is how the word 'pig' is used. To be country correct, it is the term for a very young pig. A hog is a swine that weighs over 120 pounds" (Klobner, p. 24). A mature female swine is a sow. A mature male is a boar. Barrows are castrated male pigs raised for slaughter. Gilts are immature females. Both are sold as "market hogs" at five to seven months of age and at weights of between 220 to 260 pounds. Mature hogs can grow much larger. Boars have topped one ton.

Use of the meat of the pig, known as pork, is also not without controversy. Until the early twentieth century, the hog was bred for fat, or lard, just as much as for meat. Later in that century, the saturated fats found in many types of meat were targeted as contributors to coronary heart disease. Breeding and changes in the way hogs are fed has made modern swine 30 to 50 percent leaner

than in 1950. At the beginning of the twentieth century, the lard-type hog, nicknamed "cob rollers," was so fat that its stubby legs were barely visible.

### Pushing the Chicken Fat Barrier

The leanest cuts of pork can approach the fat content of skinless chicken breast. According to U.S. Department of Agriculture (USDA) nutrition data cited by the National Pork Board, an industry group, a three-ounce roasted pork tenderloin has 4.1 grams of total fat, more than the 3.1 grams in a comparable portion of roasted, skinless chicken breast, but much less than the 9.3 grams in a chicken thigh.

Lean cuts of pork are also richer in some essential vitamins and minerals than other meats. Another USDA database lists broiled fresh pork as having .923 milligrams of thiamin, or vitamin B1, in a 100 gram serving (about 3.5 ounces). That amount is more than half of the recommended daily consumption of thiamin and ten times the amount of thiamin found in a comparable cut of beef and even more than the amount in chicken breast (0.070 mg). The body uses thiamin to metabolize carbohydrates, protein, and fat.

### The Pig's Fatty Underbelly

For all of modern pork's improved qualities, the pig is still a source of less desirable calories. As much as two-thirds of each slaughtered hog is used for processed meats—hams, sausages, and bacon. These meat products can be much higher in fat and salt than the amounts considered healthy by the medical profession.

The Center for Science in the Public Interest in the United States characterizes bacon, hot dogs, and sausage, all of which can contain pork, as among the most unhealthy foods available, recommending that consumers buy bacon and sausage that has no more than 45 percent of its calories from fat and no more than 480 milligrams of sodium per serving. In a recent survey of products sold in grocery stores, typical pork bacon (which comes from a pig's belly) had a whopping 9 percent of its calories in the form of fat. Only certain brands of turkey bacon were truly "low fat." The pork bacon was lower than turkey bacon in sodium, however, with only 170 milligrams.

Lean or fat, the swine family is an old one, geologically and in the archeological records of early human agriculture and civilization. The swine family has inhabited the earth since about forty-five million years ago, when the horrific seven-foot-high entelodont roamed central Asia and North America. Like modern pigs, entelodonts had cloven hooves and were omnivores. Their scarred fossils show evidence of fierce battles. They had much smaller brains and may not have had the social herding characteristics of modern swine. They died out twenty-five million years ago and were succeeded by smaller direct ancestors of the wild boar and modern pig.

The Javan warty pig (*Sus verrucosus*) will win no prizes for good looks or sweet temper, but it is important for preserving the biodiversity of the species. It is found only on the island of Java in Indonesia. PHOTO COURTESY OF BIOS.

### Older Than the Cow

The pig is one of the first domesticated animals: its remains in some archeological excavations have been found to date earlier than the bones of cattle. Agricultural settlements raised pigs in the Middle East at least nine to ten thousand years ago. In Jericho, one of the world's most ancient cities, archeologists unearthed domesticated pig bones in soil layers predating 7000 B.C.E. Archeological excavations in the East Indies and Southeastern Asia show evidence of domesticated swine at about the same time. The East Asian pig arrived in China around 5000 B.C.E. Some of the first written recipes for pork are from China, where the pig has been an integral part of agriculture for thousands of years, feeding on garden waste and table scraps in pens next to farm huts. Recent archeological evidence suggests that Neolithic farmers rapidly spread agriculture, and pigs, along the Mediterranean shore of Europe before 5500 B.C.E.

The pig appears again in the writing and art of first recorded history. Pork was a popular food in early dynasties of Egypt. The ancient Greeks ate pigs. The Romans were masters of smoking and salting pork. From the time of medieval Europe through colonial North America, pigs were allowed to forage for acorns, nuts, and other foods in the forest in a semi-wild state. In the fall, they would be rounded up, slaughtered, butchered, and preserved by smoking, salting, and curing. In the United States, the pig was the most popular source of meat through the nineteenth century. The westward migration of American settlers into what would become the Corn Belt in America's Midwestern states was the perfect marriage of an Old World livestock with the grain of native Americans. The diet of swine shifted ever more from woodland forage and scraps to corn. Not until the 1950s did beef surpass pork as the most popular meat in

America. Increased beef consumption coincided with the rise of industrialized cattle feedlots and post-World War II affluence. With suburbanization came the popularity of backyard grilling of steaks and hamburgers.

Many of the breeds of swine raised in North America came from England, as their names, Hampshire, Yorkshire and Berkshire, suggest. Some of these English breeds are at least four hundred years old, according to both historical records and DNA studies.

### Prolific and Efficient Meat Producers

The Spanish, too, brought hogs with them to the New World. The explorer, Hernando de Soto landed in what is now Tampa Bay, Florida, in 1539 with thirteen hogs. Three years later, the swine herd had grown to seven hundred.

This ability to multiply rapidly is a quality that endears the pig to some of the poorest farmers on earth as well as the most modern swine production complexes. A sow produces almost three litters of pigs a year, although 2.25 litters per year is more realistic on smaller, traditional farms. From each litter eight or more pigs usually survive. Sows on large commercial farms can produce nearly twenty-six pigs per year.

Not only are pigs prolific, they grow fast on modest amounts of feed. A pig easily gains a pound for every three to five pounds of feed it eats, reaching more than two hundred pounds in six months. In some intensive industrial swine farms, where pigs are confined in a small space with little to do but eat, feed efficiency has approached one pound of meat for every two pounds of feed—about the same as poultry. Pigs are much more efficient at converting grain to meat than cattle or sheep.

## PET PIGS OF NEW GUINEA

Perhaps nowhere on earth is the pig so honored and well treated as in the highlands of Papua New Guinea—at least until it is eaten.

The great anthropologist Margaret Mead visited the Stone Age tribes of New Guinea and noticed that pigs there acted like dogs. “They assume all of the characteristics of dogs—hang their heads under rebuke, snuggle up to regain favor, and so on,” she wrote in *Letters from the Field: 1925–1972*.

In this still primitive island nation south of the equator and north of Australia, the women of highland tribes rear pigs and treat them as well as their own children. They will even nurse a pig if it is orphaned. Women, children—and pigs—eat and sleep in huts that are separate from those of the men. The pigs are named, hand-fed, groomed, and fussed over if they become sick. Not until they are large are the pigs kept in a separate pen in the hut.

Eventually, though, the men slaughter some of these pigs in a ritualized sacrifice. Then the pigs become a feast for the tribal village. Pork and sweet potatoes cooked on hot stones add flavor to weddings, funerals, festivals, and other special events.

To Westerners, this may seem like bizarre, almost schizophrenic behavior. But within the context of New Guinea’s tribal cultures, it is a bit more logical.

Pigs have great economic, political, and even mystical importance in New Guinea. They are symbols of wealth. They are used to buy a bride, for example. Pigs are sacrificed to appease ancestral spirits. Some tribes consider them humanlike—and humans, piglike.

Eating one’s best friend does not seem so strange in New Guinea, where only a few decades ago cannibalism was practiced. And breast-feeding pigs is just a low-tech version of U.S. sheep ranchers bottle-feeding orphaned lambs. Valuable animals often receive loving care in many livestock-rearing cultures.

Even today, decades after Margaret Mead lived in New Guinea in the 1930s, the tribes there prize their pigs. At the turn of the twenty-first century, Jeff Tyler traveled to New Guinea for *The Savvy Traveler*, a public radio travel program and Web site in the United States.

Tyler joined a group of American and Australian tourists who visited a mountain village where a sow was ritually slaughtered. Village men, covered with black and ceremonial paint, clubbed the sow and cooked her for their guests.

Tribal warfare still continues in New Guinea. A local guide tells Tyler, “There is a reason for tribal warfare. The main reason is we fight for land. We fight for woman. And we fight for pigs.”

Until the late twentieth century, pigs were weaned from their sow from about thirty-five to fifty-six days after they were born. From a birth weight of about three pounds, they would reach a weaning weight of about forty to fifty pounds by fifty-six days. After a short period of receiving a rich “starter feed” of grains, milk products, and perhaps medication, the pigs were ready to sell to another farmer who specialized in “finishing,” or feeding hogs to market weights. Sometimes the farmer whose sows produced the pigs would keep the pigs and move them to another barn or pen to feed them to market weight in a method of production called “farrow to finish.” (Farrowing refers to the action of a sow giving birth.) Farrow-to-finish production was typical of small- and medium-size “family farms” in North America. On some farms, farrowing took place in small huts big enough for one sow, placed in a pasture of alfalfa or other digestible forage. After 1950, farrowing more commonly took place in specialized buildings or modified barns.

The farmers who specialized in farrowing would cross several breeds of swine in order to produce stronger,

healthier pigs that grow faster. This benefit from cross-breeding was called hybrid vigor. Farmers who specialized in feeding pigs for slaughter began to separate them by sex, so that the males and females could be given different feeding rations tailored to the nutritional needs of each sex.

### Commercial Complexity

In large commercial farms, swine production is even more complex, having moved beyond the traditional one-site or two-site production system. On these farms, pigs are weaned at much earlier ages, sometimes when only ten to fourteen days old. This technique, called medicated early weaning, was developed in Britain in the 1980s by veterinary medicine professor Tom Alexander at the University of Cambridge. Alexander discovered that very early weaning could prevent a sow from passing certain swine diseases to the next generation of piglets. Weaned pigs are moved to separate nursery buildings, at enough distance to lessen the chance of infection by wind-born disease agents. The pigs are usually held in the nursery

for seven weeks. before they are moved to another set of buildings for the “finisher-production” stage, where they reach slaughter weights.

In large pig farms, pigs are kept in small groups that remain isolated from older pigs. By avoiding the mixing of pigs after they are weaned, the risk of spreading diseases is lowered. Each week, while one group of pigs is moved from the site where they were born to a nursery building, another group is moved from a nursery to a finishing building, and yet another is moved out of a finishing building to the slaughter plant. After each group is moved, the building is washed and disinfected. To make this system work like a well-oiled machine, the farm or hog producing company must have 12,000 to 24,000 sows. This system can produce more than 600,000 market hogs a year.

### **Industrialized Production Spreads across the Globe**

This multisite system of production has existed along with the more traditional ones, in which farmers raised only a few hundred or a few thousand pigs for slaughter. But at the start of the new millennium, multisite production was rapidly taking over the industry. In Corn Belt hog-producing states, individual families that ran grain farms still fed hogs, but only in the second and third stages of multisite production. The families no longer owned the pigs. Instead, they raised them for large companies, much as local entrepreneurs run franchise outlets for fast-food chains. The pigs were owned, from birth through slaughter, by large companies, including packers. The parent animals in this system are complex proprietary mixtures of breeds owned by a handful of multinational companies. By the late 1990s, more than half of U.S. production was in some stage of this “vertical integration,” meaning that each step in hog raising is owned or controlled by one company. The multisite pig production system was becoming global, existing not only in the United States and Britain, but also in Canada, Mexico, Brazil, Chile, Spain, Germany, Poland, Italy, China, and France.

Many of these countries are also the top producers and consumers of pigs. China is the leader, producing 43.2 million metric tons of pork in 2002, more than half of the global production of 85.2 million tons. The European Union was a distant second, with 17.8 million tons. The United States ranked third, producing 8.7 million metric tons of pork. China’s livestock practices supply the main reason the world eats much more pork than other meats. Of the world annual beef production of about fifty million tons, China raises only 5.8 million tons of beef.

### **Pigs Led to Slaughter**

Just as pig farming has changed, so has the slaughter of hogs and the curing of pork. Hogs are trucked to packing plants where they are unloaded, held in pens to fast, and then slaughtered, most commonly by stunning with

a high-voltage electrical shock. Then the carcass is hung by the hind legs from an elevated conveyor line, bled, and cut apart. The treatment of hogs before slaughter is both an economic issue as well as one of humane treatment. If the animals are frightened and stressed for a long period of time, lactic acid builds up in the muscles, affecting meat quality. Some breeds of pigs are more susceptible to stress than others and can produce pale, watery fresh meat. The swine industry has dealt with the problem two ways. First, it has bred hogs to exclude lines that produce poor quality meat when stressed. Second, the packing industry is changing slaughter methods to treat hogs more humanely, which also reduces stress.

Colorado State University animal scientist Temple Grandin has devoted her life to making the last few minutes of cattle and hogs as pleasant as possible. As a result of her studies of how animals react to new environments, both farmers and slaughter plants are starting to move pigs through curved chutes onto trucks, and out of trucks into the packing plant to prevent pigs from witnessing what lies at the end of the line. Pigs are instinctively frightened when forced into a confined space. In Denmark, slaughter plants are experimenting with stunning hogs with carbon dioxide gas, which may be less stressful than electrical shock.

Refrigeration is the modern method of preserving pork, even for most ham and bacon, which is injected with brine, smoke flavoring, and, usually, sodium nitrite to give the meat a pink color and to protect against the growth of toxins responsible for botulism.

### **The Art of Curing and Cooking Pork**

Traditional methods of air curing, which may date to pre-Roman times, are still used in China, Europe, and the American South. Hams are made by covering the meat, usually from the upper rear leg or hip but sometimes from the shoulder, with salt, sometimes sugar, and flavorings for several days in a cooler. The meat is then smoked at room temperatures in a smokehouse for about ten days and allowed to cure for at least six months. Before cooking, traditional air-cured hams should be soaked in cold water to remove excess salt.

Exactly why so much of the pig is cured and made into bacon and ham, while less beef and lamb is consumed as dried or smoked products may be a question for archeologists, not historians. One theory about the popularity of cured pork, offered by the National Pork Board, is that pork is a mild meat that, having less flavor than some meats, readily takes on added flavors.

Fresh pork faces another obstacle when compared to flavorful cured meats. As it became leaner in the late twentieth century, the potential to make fresh pork less palatable by overcooking increased. With less fat in the meat, overcooking can make pork taste very dry. The habit of overcooking stems from consumer fears that rare pork risks exposure to the parasite that causes trichinosis.

The parasite has been virtually eliminated from pork in most developed countries. To be safe, food experts recommend cooking pork until internal meat temperatures reach 170 degrees Fahrenheit, or piercing to the center of a cut of cooked pork. If the juices run clear, the meat is done, and no further cooking is needed.

### Fighting the Flavor Drought

Dry pork is just one factor causing a growing reaction against raising pigs in the industrial system. As North Americans and Europeans consume more natural and organic vegetables, grains, and dairy products, a market is developing for natural and organic meats raised on smaller farms, sometimes with methods that animal welfare organizations consider more humane.

In the United States, one company, Niman Ranch of San Francisco, California, hires farmers to raise pigs without antibiotics or growth hormones for sale to natural foods stores and upscale restaurants. These farmers raise pigs in pastures or on straw bedding in barns and sheds and periodically submit samples of meat to a taste panel to make sure that it is not too lean to be palatable. They use swine breeds that are not quite as lean as the crossbred hogs in large multisite hog businesses. After tasting this type of pork, *New York Times* food writer Marian Burros reviewed it as “so delicious it needed no seasoning beyond salt and pepper. . . . [The] meat was superior heirloom pork, suffused with a bright clean flavor, with none of the unpleasant aftertaste that pork often has” (September 1999).

Dry pork is less of a problem in China, where much of the pig meat consumed in that country still comes from small farms and traditional breeds that are not as lean as those from Europe. The western provinces of China, known for spicy Szechwan dishes, also produce a type of ham, Yunnan or Xuanwei ham, that is exported to Southeast Asia and Europe. Mu Shu pork, consumed in the northern provinces near Beijing, is a dish that is popular in the United States as well. This rural Chinese dish is a mixture of sautéed pork and diced vegetables that is wrapped in small, steamed pancakes and dipped in a sauce. Unlike in the West, where pork is eaten by itself, in China most recipes use it sparingly, cut into small pieces and mixed with other ingredients. Blending flavors of many foods, an important principle of Chinese cuisine, has stretched supplies of pork and other meats in times of scarcity. The preciousness of pork may also be why no part of a pig is wasted in China. Even the head of the pig continues to be served by some pushcart vendors and urban restaurants.

### Fear and Loathing of Pigs

As beloved as pork is in many cultures, the pig is despised in the traditions of others. Many theories exist to explain why Islam and Judaism consider the meat of pigs unclean. To some followers of these faiths, the abhorrent nature of pigs is obvious. The animals often wallow in mud and

look dirty. But pigs, unable to sweat, wallow in mud as an efficient way to stay cool. Nevertheless, their breeding conditions may have created a social stigma. Animal scientists M. Eugene Ensminger and R. O. Parker point out that because “close confinement was invariably accompanied by the foul odors of the pig sty . . . early keepers of swine were often regarded with contempt” (Ensminger and Parker, p. 1 ).

Anthropologist Marvin argues that the pig’s downfall in the Middle East was economic. Pigs are costly to raise in the climate of the Middle East. They are more difficult to herd than the sheep and goats favored by the desert nomads who quickly adopted Islam. And there is evidence that over the past ten thousand years, the environment in the Middle East grew less hospitable for animals originally adapted to foraging in forests.

Harris contends that for Jews, “the food laws of Leviticus were mostly codifications of traditional food prejudices and avoidances” (Harris, 1985, p. 79). A book of the Torah, Leviticus was written in 450 B.C.E., long after swine herding and consumption had lost prestige in many other ancient near eastern cultures as well as in ancient Israel. He finds even more support for his theory in China, where pork-disdaining Islam failed to penetrate far. There, the pig complemented an agrarian ecology, eating stems, leaves and scraps from many vegetable crops, and in turn, being eaten.

Archeological digs in the Middle East give evidence that the pig was once worshipped as well as eaten. In early stages of Phoenician, Egyptian, and Babylonian civilizations, people freely ate pork. But as those civilizations matured, pork fell from favor. When the Greek historian Herodotus visited Egypt before 430 B.C.E., he saw that “the pig is regarded among them as an unclean animal so much so that if a man in passing accidentally touches a pig, he instantly hurries into the river and plunges in with all his clothes on” (quoted in Harris, 1985, p. 83).

The anthropologist Carlton Coon attributes the demise of pigs in this region of the world to deforestation and population increases. At the beginning of the Neolithic period, pigs could root in oak and beech forests. As human population density increased, Coon argues, the forests were cleared to make room for more farms, especially olive groves, and in times of famine and scarcity, pigs competed with humans for life-giving grain.

### Pigs Provide More Than Meat

In the future, the economic relationship to cultural and religious taboos may be tested if pigs become more than a source of meat and go on to save more lives. Besides providing pigskin leather and byproducts with industrial uses, pigs are already a source of pharmaceuticals, such as insulin. Since 1971, pig heart valves have been used to replace damaged human heart valves. Pig valves are treated and contain no living cells, preventing rejection by the human immune system. Soon, genetic manipula-

## SPAM

Spam might be described as the Woody Allen of the meat world. Like the American film actor, this small 12-ounce can of pork is a commercial success thriving on self-deprecation. In enticement, the rectangular block of pink processed meat sliding from the can onto a platter cannot contend with a juicy steak or a real ham. Consumer advocates cite it as an example of a high-fat food. The Oxford English Dictionary defines the adjective, spammy, as "consisting or tasting chiefly of 'bland' luncheon meat. . . mediocre, unexciting."

Spam drew widespread ridicule in the 1970s in a comedy skit on British television's *Monty Python's Flying Circus* when a Spam-pushing waitress was drowned out by a group of Vikings singing "Spam, spam, spam, spam. Lovely Spam! Wonderful Spam!" More recently, this trademarked brand of canned meat received a dubious tribute in the adoption of the term "spam" to denote unwanted e-mail, or unsolicited electronic mail messages. The association of the term with a food product may, in fact, have been overwhelmed by its new slang definition.

Even so, Hormel Foods Corporation, the maker and inventor of the original Spam, has profited on the sale of some five billion cans of the stuff, marketed in roughly one hundred countries, since its introduction in 1937 as "Hormel Spiced Ham." The Austin, Minnesota-based food company, founded in 1891 as Geo. A. Hormel & Company, pioneered the production and sale of canned hams in the 1920s. A New York actor, Kenneth Daigneau, won a naming contest by calling it Spam.

Spam is made from ham, pork shoulder meat, and a secret mix of spices. World War II turned this depression-era canned luncheon meat into a global product. Spam helped keep Russian troops from starving. It cheered the British palate. And it drew ribbing from U.S. forces in the South Pacific, where they named one encampment "Spamville." After the war, U.S. president Dwight Eisenhower admitted that he, too, ate his "share of Spam along with millions of other soldiers" (Hormel website).

In recent years, Hormel reports selling one hundred million cans of Spam annually in the United States, and

another forty-two million overseas. Hawaiians are the top per capita consumers of Spam in the United States, at more than four cans per consumer a year. South Korea and the United Kingdom are the top overseas buyers of Spam.

In 2001 Hormel opened a 16,500 square-foot SPAM Museum in Austin, Minn. The following summer, it planned a media event with television stars; Barbara Billingsley, who played June Cleaver on the series *Leave It to Beaver*, was invited to present her favorite Spam recipe, "Overnight SPAM & Broccoli Cheese Strata."

Spam's notoriety has achieved recognition. An original Spam can is in the Smithsonian Institution's National Museum of American History in Washington, D.C. Spam inspired a book of haiku poetry, *Spam-Ku: Tranquil Reflections on Luncheon Loaf*. Meanwhile, the company valiantly fights misuse of the word "spam" for what it calls "unsolicited commercial email (UCE)." Hormel's "official SPAM Home page. The one in good taste," gives company policy: "We do not object to use of this slang term to describe UCE, although we do object to the use of our product image in association with that term." Hormel also prefers that the name of its trademarked food be capitalized as SPAM, while "spam" as junk e-mail should be lowercase.

The company seems to recognize that its original Spam is high in fat. With 140 of a serving's 170 calories coming from fat, those eating half of a can would have nearly exceeded the recommended daily intake for saturated fat and sodium. In response to these concerns, Hormel began offering SPAM Oven Roasted Turkey, SPAM Smoke Flavored, SPAM Lite, and SPAM Less Sodium with "the same great taste."

tion may allow transplants of whole, living organs from pigs to humans. Pigs offer an advantage over other animals by closely matching those of humans.

Many scientific barriers remain, but in early 2002 two rival biotechnology companies announced a major step toward xenotransplantation (the transplanting of an-

imal organs into humans). Both had cloned pigs that are missing a gene that causes an immune reaction in humans. The offending gene sets off production of an enzyme that makes a sugar that human bodies recognize as foreign. Pig organ transplants without the gene may be less likely to be rejected.

Trade card (circa 1883) showing a prizewinning Chester White boar named "Kennett." This breed of hog was raised primarily for lard, which explains why there is so much fat on the animal. ROUGHWOOD COLLECTION.

Even in cultures that do not view pigs as unclean, xenotransplantation has vocal opponents, including animal rights activists and others who worry that this technology may introduce new viruses from pigs to humans.

### The Pig in Myth

It remains to be seen whether pigs will physically become parts of humans. Symbolically, they have been transplanted into human culture for centuries, in medieval Europe, modern China, and ancient Mesopotamia. Pigs first symbolized deities, and later, human weaknesses and strengths.

In China, the pig is one of twelve animals symbolizing a year in a twelve-year lunar calendar. According to Chinese mythology, all animals were invited to race for this honor. A year was assigned to the first twelve winners, as each one finished. The pig came in twelfth. Just as westerners who believe in astrology tie personality traits to signs of the Zodiac, the Chinese attribute personality traits to the year in which they were born. Those born in the Year of the Pig (also called Year of the Boar) are said to be easygoing, sincere, tolerant, and honest. They are also considered naïve. Naïveté was linked to pigs in Homer's *Odyssey*, when Ulysses' men were turned to pigs by the sorceress Circe. While the men themselves were naïve, their behavior even before their conversion was almost piglike. They were attracted by Circe's sweet voice and lulled to complacency by her rich meal. Homer seems to use this tale to impart a sensuality to pigs, as well as a pig-likeness to the mariners. The pig was sacred to Aphrodite and an important image in Celtic mythology.

A vision of a sacred white sow was part of the legend of the founding of Rome. In Christian Europe, the sensuality of pigs came to take on a harder edge, an association with gluttony, perhaps because Jesus is depicted as casting demons into swine. The strong personality of

the squealing, ever-present pig became a convenient device for the writers and fable makers of Europe in the eleventh through thirteenth centuries. Moralized fables called bestiaries made use of pigs to symbolize the Seven Deadly Sins, not just gluttony, but also pride, covetousness, lust, envy, anger, and sloth.

Pigs are recognized as intelligent, exhibiting a range of emotions and behaviors in real life just as in fables and mythology. For centuries, farmers have found herding and catching pigs difficult. This intelligence makes pigs a priority for animal rights organizations that challenge the methods of confining pigs in intensive industrial production, in which pigs are kept on concrete floors with slats that allow for the collection and flushing of manure into earthen lagoons or metal holding tanks.

Modern confinement appears clean compared to hogs wallowing in outdoor pens. The use of metal crates to restrict sow movement is humane, say the system's defenders, because it prevents newborn pigs from accidentally being crushed by a heavy sow. The U.S. National Pork Board's position on animal welfare is that "because the welfare of their animals directly affects their livelihood, pork producers work to ensure their animals are treated humanely. Anything else would be self-defeating." Some farmers are, in fact, beginning to revise their methods.

### Attempts to Treat Pigs More Humanely

At the urging of farmers in Sweden, that nation in 1986 banned the routine use of antibiotics in raising animals for food. In 1988, it required that all animals used for food be allowed to behave naturally. Small metal stalls that restrict the movement of sows about to give birth were banned. Minimum space requirements for sows and boars were established for hog buildings. If pigs were housed inside, straw bedding was required, to absorb manure, to keep pigs clean and dry, and to give pigs a place to root, a natural behavior. In the United States, the Animal Welfare Institute, founded in 1951, has worked with farmers to set up voluntary use of Swedish pig-raising methods.

Straw bedding must periodically be moved onto farm fields to keep pig buildings clean. This requires labor that larger intensive farms may not have. Large farms flush manure with water into lagoons or tanks. That manure is also spread onto farmland as fertilizer. But critics charge that current environmental standards in the United States do not require the manure to be spread over a wide enough area and allow it to eventually build up excessive amounts of nutrients in soils that can wash into streams or contaminate groundwater. Spills of manure have already caused fish kills and stream pollution in Midwestern states. In 1999 a large hog-producing company in Missouri, Premium Standard Farms, agreed to pay \$25 million to settle a lawsuit accusing it of violating the state's Clean Water Act.

## Clearing the Air?

Untreated pig manure stored in open-air lagoons or tanks just plain stinks to neighbors and rural residents. In part because of complaints from rural voters, the Iowa legislature passed a law in 2002 that will require manure from confined hogs to be spread over more land. In a state with five times as many pigs as people (nearly fifteen million), the Department of Natural Resources is also developing a scoring system that considers community and environmental needs before the department approves construction of any more large hog buildings. Yet the law gives local governments no control of hog farm growth, critics say.

Adding low levels of antibiotics to pig feed may be the most serious environmental challenge from large-scale confined livestock. Feeding antibiotics has fostered antibiotic-resistant bacteria in livestock, including pigs. These antibiotic-resistant bacteria can be transferred from animals to people. Resistance genes may also transfer from one bacteria type to another more dangerous one such as salmonella.

In 1999, the Center for Science in the Public Interest, the Union of Concerned Scientists and several environmental groups petitioned the U.S. Food and Drug Administration to rescind the approval of agricultural use of antibiotics when their use endangers human health. Other groups supporting that view include the World Health Organization, the Centers for Disease Control and Prevention, and the American Public Health Association. Some of these antibiotics have been banned from feed in Europe.

Hygiene, humane farming, and health benefits and threats are among the many controversies surrounding the controversial pig, an animal that is likely to continue to feed the minds and stomachs of billions of humans as it has already for thousands of years.

Dan Looker

**PIZZA.** Although it is one of the world's simplest and most popular foods, pizza is oddly difficult to define. Centuries of evolution have transformed it from the patties made of mashed grains that were its earliest antecedents into a dish that, though related to those early grain cakes, is almost unrecognizable as their descendant. Most significant is the change in the primary ingredient, from various coarse grains to a solely wheat-based dough, and eventually to a dish made almost exclusively with white flour.

However, though pizza has taken many forms, and its composition, toppings, seasonings, methods of preparation, and the equipment used to make it have altered radically over the years, it has usually been a flatbread baked at high temperatures.

## Early History of Pizza

For millennia, pizza, a food of various origins and multiple styles, has played an important role in the diet of those who inhabited the land now called Italy. Neolithic nomads, the Etruscans from the North, and the Greeks from southern regions were the three earliest societies to develop pizza prototypes, for example, *focaccia*. Each group made small adaptations that changed the original product into a slightly more refined dish.

As early as the Stone Age, Neolithic hunter-gatherer tribal groups foraged throughout what would become Italy for wild grains, among them wheat varieties such as emmer and einkorn, as well as barley. Commonly first soaked or boiled, these grains were mashed into pastes and cooked on hot stones over open fires.

Later, around 1000 B.C.E., the Etruscans, a people of uncertain origin, introduced their flatbread to Northern Italy. Like the Neolithic tribes before them, the Etruscans pounded their grains. However, unlike their predecessors, the Etruscans baked their mash on stones and buried the stones in the ashes, creating smoky tasting bread. They further elaborated on the primitive Neolithic flatbread by seasoning the mash with oil and herbs after baking it. Though little more than rough slabs of cooked grain, these Etruscan flatbreads, among the earliest forms of this type of food documented, were often used as dough "plates" in lieu of dishes.

The Greeks, who had superior baking skills and technology, further advanced and elaborated on pizza during their 600-year (730–130 B.C.E.) occupation of the southern areas of the Italian peninsula. Like their predecessors, they produced a grain-based mash, but instead of placing the toppings on the cooked breads, they placed

## DERIVATION OF THE TERM “PIZZA”

The word “pizza” simply means “pie” and is a Southern Italian derivative of the Roman term *picea*, both a bread itself and the ash-blackened underside of the Roman bread called *placenta*. Some say this term eventually evolved into “piza,” then “pizza.” Similarly, another flat bread, *pitta*, thought by some to have been introduced to southern Italy during the sixth-century Byzantine conquest, may also have influenced the modern day pronunciation of “pizza.”

them on the raw dough prior to baking, perhaps to ensure a more highly flavored dish. *Plakuntos*, for example, flat, round breads, were made with various simple toppings, among them oil, garlic, onion, and herbs. Additional Greek contributions included the use of ovens, instead of open fires, and the development of kneading, which produced a more digestible bread. Evelyn Soman highlights early excerpts from Plato’s *Republic* that refer to meals created from barley flour kneaded and cooked into “cakes” with olives and cheese (Soman, 1984, p. 5).

Although it is not firmly established, many also credit the Greeks with improving on the knowledge of leavening agents that came down to them from the Egyptians, and then introducing yeast into their own flatbreads. The Greeks also added a raised rim to the outside of their dough circles, to stabilize their dough “plates,” making them easier to hold, and, perhaps, even helping to keep the toppings in place.

Much later, the Romans combined the Etruscan and Greek techniques to create the pizza antecedent most like the pizza known today. They valued the intense heat the Etruscans achieved by baking their flatbreads below the fire, and they appreciated the Greek idea of preseasoning the dough. They also modified the Greek *plakuntos*. Known to them by the Latin term *placenta*, their adapted bread, though still round, was topped with cheese and baked on a wood-burning hearth. *Laganum*, a light, thin wafer bread, was also cooked on the hearth.

If the Greeks and Etruscans were primarily responsible for creating the prototypes of what was to become pizza, and the ancient Romans were responsible for improving it, it was largely the Neapolitans who brought it fame. Probably not coincidentally, the Neapolitans were responsible for the addition of the ingredient most commonly associated with pizza today—the tomato.

No one is sure of the precise reason, but it took well over two centuries from the time the New World tomato was introduced to the continent of Europe during the

Columbian food exchange for Neapolitans, and various other inhabitants of the peninsula, to begin consuming tomatoes in quantity.

There are several theories about why adoption of a fruit that has almost come to symbolize Italian cuisine took so long. One argues that it was because tomatoes were believed to be poisonous, another that the earliest tomatoes were inferior and, therefore, eaten only in modest amounts until quality improved enough to make the fruit genuinely popular. In the area of Naples, for example, a key moment appears to have come in the middle of the eighteenth century with the development of a pleasing, large, and sweet tomato. The fruit quickly became the mainstay of Neapolitan pizza toppings.

It was also around this time, during the era of Bourbon King Ferdinando I and Queen Maria Carolina, whose empire included Naples, that one of the earliest pizza legends took root. In one version of the story, the queen (Marie Antoinette’s sister and the daughter of Empress Maria Teresa of Austria) is said to have been described by the king as having “common tastes,” apparently a quality thought to explain her love of pizza, a dish of the people. It is, however, a measure of the confounding nature of pizza lore that in a variant of the story, it is the king who relishes pizza and the refined queen who does not understand his passion.

Whichever of their majesties was the real enthusiast, the object of desire was probably flavored with lard (a less expensive alternative to oil), tomatoes, salt, and sometimes tiny eels, anchovies, or sardines. Over time, craving for this pie became so great that either the king, to gratify his wife’s yearning, or the queen, to gratify the king’s hunger, had a pizza oven built at the Capodimonte palace, so they could make the dish at home, an act that brought the pie even more attention. Pizza became the fashion, and other nobles followed suit, building pizza ovens where they lived.

However, it was not until 1889, a time when yet another ingredient is purported to have become part of the equation, that pizza began its march toward wide celebrity. It was then that inspiration is said to have struck Raffaele Esposito, a noted Neapolitan *pizzaiolo* (pizza chef), who decided to pay homage to Queen Margherita and King Umberto I of Savoia, the ruling house of Italy, by adding mozzarella to the traditional tomato and basil pie. The combination of red, white, and green suggested the colors of the Italian flag and saluted the United Kingdom of Italy, a gesture that for patriotic reasons is said to have made the pie a favorite of the queen.

Though most stories of origin give Esposito credit for adding cheese and thereby inventing the tri-color pizza, still known as Pizza Margherita, others deny it, believing that mozzarella had been used earlier. There is no doubt, however, that Esposito popularized the “made for each other” combination of cheese, dough, and tomato that produced a dish even more delicious than

before, thereby setting the modest pie on a course to fame that he could never have imagined.

In Italy today, pizza exists in a number of regional styles, of which two of the most famous are the Neapolitan and the Roman. Both schools knead the dough, but *pizza alla Napoletana* is round, has a high border, takes diverse toppings, and is generally sold in pizzerias, while *pizza alla Romana*, also called *pizza bianca*, is more or less rectangular, often as much as a meter long, topped only with oil and salt, and sold by weight, primarily in bakeries and groceries, according to the size of the piece requested. Many other regions of Italy—Sicily, for example—also have distinctive versions of pizza. However, the popularity of the dish has meant that the styles are not always confined to the geographical areas in which they were created. Neapolitan-style pizza, for example, can be found in many places in Italy, as can *Pizza alla Romana*.

### The Birth of the Pizzeria

From the beginning, pizza was rarely prepared at home because few people had the skill to stretch the dough properly or the money to build a wood-fired oven in which to bake it. Consequently, it was almost always bought from small stalls or from pizza sellers carrying their aromatic wares through the crowded Neapolitan streets. Some more elaborate open-air pizza stands offered slightly more upscale options, along with makeshift seating, but it was not until 1830 that the first documented pizzeria, that is, an inexpensive gathering place specializing in pizza and equipped with wood burning stoves, began doing business in Naples. It was called Port'Alba. Still in operation, its opening marked the birth of a style of eating establishment now known around the world.

The notion of a pizzeria as a fast-paced, economical restaurant has continued. In fact, the institution of the pizzeria is as critical to its vast global appeal as the food itself is.

### The Development of Pizza as an American Icon

Although pizza is not exclusively Italian in origin, there is no question that from a cultural standpoint, it is an iconic food of Italy. Italians “own” this delicacy. Nevertheless, pizza in the United States may also be considered an icon food, perhaps even more so than in the land of its birth. The dish has become an American institution—embracing food-on-the-run, corporate enterprise, and American ingenuity, and it may fairly be said to be as representative of American foodways, food customs, and food choices as it is of Italian ones.

Pizza arrived in the United States in the latter half of the nineteenth century, along with a wave of largely southern Italian immigrants. Soon many of those immigrants were making their livelihood operating bakeries and groceries where they sold pizza alongside produce and staple ingredients.

The first real American pizzeria, opened in New York City in 1905 by Gennaro Lombardi, was located in

Pizza has evolved from a relatively simple peasant dish into a vast array of preparations, including “gourmet” and vegetarian interpretations. © GERALD ZANETTI/CORBIS.

Manhattan, at 53½ Spring Street. As with other early pizzerias, the clientele was composed predominantly of southern Italian immigrants, who wanted to eat their own dishes in a familiar and homey atmosphere. However, after World War II, when GIs returned from Italy well acquainted with pizza and other Italian foods, they forged a new and growing market for those foods.

As is the case with so many other traditional Italian foods, pizza underwent significant changes in the United States. Thanks to the American postwar emphasis on excess and increased portion size, as well, possibly, as the desire of poor Italian immigrants to eat more copiously than they had been able to do at home, the delicate Neapolitan pizza was transformed. Formerly lightly embellished with tomatoes and other toppings, it was increasingly laden with an abundance of meats and cheese, sometimes creating slices weighing close to a pound.

Other differences developed in the United States, too. The pie acquired regional American styles, New York, Chicago, California, and New Haven the best known among them. New York pizza is cheesy and gooey, with a high, dense border and medium-thick crust; it can be bought by the slice or whole. California style has a very thin crust, adorned with an array of toppings unlikely to be found in Italy, ranging from goat cheese to tandoori chicken, to *moo shu pork* or bacon with pineapples. Chicago style is “deep dish,” prepared in a pan, and based on a thick-crust pizza. New Haven style is somewhat similar to New York pizza, but is known especially for its white clams.

In addition to the regional pizzas available in the United States, ethnic variations exist. Because the costs of opening a pizzeria are relatively low compared with those of opening a more formal restaurant, the business of pizzerias has long attracted immigrants. In addition,

## PREPARATION OF THE PIZZA

Pizza preparation is simple, with few rules dictating a sublime product. The dough is made only with flour, natural yeast or brewer's yeast, salt and water. Dough is then kneaded either by hand or mixer, and the dough is punched down and shaped by hand.

Although most pizza is served as a round pie, a folded over variation, known as a calzone (or pants leg, so called because of the calzone's resemblance to the loose trousers once worn by Neapolitan men), is also popular. Originally from Naples, as is pizza itself, this style of turnover appears elsewhere as a *mezzaluna* (half moon) or *panzerotti* (stomachs). Additionally, there are double-crust, or stuffed, pizzas filled with all sorts of meats, fish, vegetables, and cheeses. They are referred to by the same name as flat pizzas, but some argue that such famous examples as pizza *rustica* and pizza *pasqualina* come out of a different tradition entirely, one that dates back to the pies of Medieval times. In addition, there is a rolled variety of pizza called *bonata*, known to Americans as *stromboli*.

While standard toppings—among them, sausage, ricotta cheese, peppers, mushrooms, and meatballs—vary from region to region and city to city, the dough remains quite similar. Although any flour may be used, prized pizza is prepared using the high-gluten variety that produces strong dough that rises easily. Such flour, along with yeast, water, salt, and olive oil, creates the perfect dough.

### Equipment

- Commercial pizza oven—may be wood, coal, gas, or electric, but ideally should achieve a temperature of at least 700°F. Pizza stone or quarry tiles (to supply intense heat) simulate a pizza oven's temperature for home use.
- Pans—pizzas are either first baked in round pans to secure the shape or baked directly on the stones or oven floor.
- Pizza peel or paddle—an elongated wooden or metal paddle used to place the pizzas in and remove them from deep ovens.

because pizza seems to be a blank slate inviting adaptation, Arabs, Chileans, Israelis, Greeks, Indians, and a diversity of other pizzeria owners often serve ethnicized versions next to traditional Italian pies. Depending on ownership, the menu may offer curried double-crust pizza, or pizza topped with feta cheese, or falafel. (It should also be noted that the same process occurs abroad.

Pizza flourishes in Tokyo, Shanghai, Tel Aviv, Moscow, and other cities around the world. Though still associated with Italy or, perhaps, even the United States, the pizza itself often bears minimal resemblance to the original dish.)

Once a handcrafted art form, pizza in America (and often elsewhere) is now mass-produced by an overabundance of pizza chains that incorporate the technological advances featured in the monthly print-and-on-line trade journal *Pizza Today*. In 1951, just ten years after the Minneapolis-based members of the Totino family founded one of the first Midwestern pizzerias, that family initiated the frozen pizza business. In 1953, 100,000 stores were offering refrigerated or frozen pizza (Trager, 1966, p. 544), and at least 15,000 pizzerias similar to the Totino original were operating in the United States. Shakey's opened in 1954, Pizza Hut in 1958, Little Caesar's in 1959, and Domino's in 1960. In 1973, perhaps cashing in on the American attraction to anything French, Stouffer's introduced frozen French bread pizza.

In 1982, the California chef Wolfgang Puck joined the California food revolution and introduced his super thin-crust, "designer" pizzas, featuring among other choices, a smoked salmon variety. This marked the beginning of the "anything goes" upscale and innovative pizza, completely characteristic of quintessentially American iconic foodways.

**PLACES OF CONSUMPTION.** A discussion of places of consumption should begin where food has been consumed since the beginning of humankind, in the home. In the twenty-first century in most countries the home remains the primary location for eating. That is not to say that the nature of the food eaten in the home has remained constant or that the preparation of the food has not changed. Even the formality and regularity of dining in the home was altered in the twentieth century.

During the nineteenth century and the early twentieth century in the United States, dining at home was usually regular (breakfast, lunch, and dinner) and occurred at the kitchen table or in the dining room. Food was often seasonal. The heaviest meal (dinner) was at noon or, if the breadwinner worked outside the home, in the evening. If the lighter meal occurred at night, it was called supper. The fare did not include a great deal of variety.

The improvement in the means of transporting food and people as well as the advancements in preservation markedly increased the places of consumption and the types of food consumed in much of the world. With modern transportation and refrigeration in mind, this overview examines places where people eat, starting with the contemporary home, moving to the world of work, touching upon the varying modes of travel and places where people play, and concluding with the increasingly vast array of dining-out possibilities.

### The Home

The sit-down meal three times a day at set times is disappearing. Although such mealtimes happen, they are becoming a rarity in technologically advanced societies, where mothers and fathers work and children come and go more freely. The family eats when there is time and often not together. Dress is casual. People eat at the

The interior of a typical nineteenth-century Viennese restaurant by artist Karl Josef Richard Zajicek. © ARCHIVO ICONOGRAFICO, S.A./CORBIS.

kitchen counter, in a breakfast nook, in front of a television, in bed, on the porch, on a patio, on a lanai, or in the yard. The dining table has become a catchall that is only cleared for company. Food is seldom prepared from "scratch." More often than not the food is semiprepared in the cupboard, the refrigerator, or the freezer. Ready-to-eat meals are found in supermarkets and delicatessens.

The mainstay of the diet in the United States and most other countries of the world, is the sandwich, which competes with the rice ball in Asia. It can be prepared quickly and can be eaten in any room or while walking. Traditionally, bread forms the basis of the meal, but the tortilla wrap is making inroads. Fillings vary, and the most common in the United States are peanut butter and jelly, tuna, meat slices, and cheese. Each of these fillings alone may form the basis of the sandwich, or each may be combined with one another, other fillings, vegetables, and condiments.

Take-out meals may be purchased from most restaurants, and ethnic foods, such as Chinese, Thai, and Mexican, are especially popular in the United States. Pizza is a favorite either ordered and delivered or frozen ready to heat and eat. Barbecues are frequent in sunny climates and are not unusual in colder ones, where the cook must bundle up to prepare the main course.

Entertaining at home is usually informal. The dining table, kitchen counter, or cooking island may serve as a buffet table. While complete meals may be served, "heavy" hors d'oeuvres are not uncommon because guests can consume their meals standing. If dinner guests are seated for a traditional meal, the number invited is usually limited to one or two couples. This is not the case for family gatherings, when substantial meals are served and guests find seating either at a large table or throughout the house.

In sum, whether preparing food for the family or for guests, contemporary home cooking utilizes the many available shortcuts to delicious cuisine. It should be noted that worldwide the less advanced the society, the more traditional the meals at home.

## The Workplace

For most of the workers of the world, lunch is the meal most frequently consumed at work. Traditionally it was brought to work in a paper sack or a lunch pail. Among blue-collar and white-collar workers the principle source of nourishment was the sandwich. In Asian countries the rice ball was most common. While this custom continues to some extent in the twenty-first century among blue-collar workers, white-collar workers generally purchase their lunches either in the workplace or nearby.

White-collar workers usually work in office buildings with many other personnel. Frequently the company that employs them provides a cafeteria or food machines for their convenience. A lunchroom is usually available with hot and cold running water, a refrigerator, and a mi-

crowave. Executives often have their own dining room, which comes with a dress code, a view, a higher cost, and presumably better food. Until the late twentieth century it was expected that food would be consumed away from the desk. This custom has been relaxed, and many office employees are allowed and encouraged to eat while working through their lunch hours.

Office workers have food choices outside their buildings. Many restaurants cater to the lunch crowd and offer quick service and specials. In areas where the work population is not so large and the location is more remote, lunch trucks service the workers. As in the office building, dress for the most part is working attire. Many blue-collar workers may bring their lunches because, particularly with construction workers, sites vary and the nature of the work produces a real appetite. Factories usually provide cafeterias, and lunch trucks are regular fixtures.

In the United States coffee is considered a necessity at any place of work. The coffee break is usually for fifteen minutes midmorning and midafternoon, even if the food consumed is tea, soda, or a snack. In a traditional office coffee was consumed in a break room. By the late twentieth century it was most likely enjoyed at a desk. Whether fresh-brewed or freeze-dried, coffee is provided when possible, often twenty-four hours a day. If that is impossible, most workers bring their own in appropriately insulated containers. While work sites around the world have similar customs, some substitute tea, and the younger generation prefers soft drinks.

Some work sites are so remote or removed from modern technology that food consumption requires high-tech preparation. The U.S. military frequently runs into this situation when its troops are in the field. The dried food of the past has been replaced by meals ready to eat (MRE). Whether eaten in a jungle or a desert, the MRE has generally received a positive response. Astronauts also dine in outer space on compacted and non-perishable food. Interestingly, advances made for consumption in these unusual sites have found their way into the modern home as convenience foods.

Some workers earn their living by driving, and they find restaurants along the highways as well as in the towns and cities they drive through. Although truck drivers can eat in their trucks, many of them want to get out of their drivers' seats and park their long, cumbersome vehicles. Consequently a place of consumption was created just for them, the truck stop. Known for its large portions, filling food, and affordable prices, the truck stop services truckers and other travelers interested in a casual yet substantial meal.

Many jobs are combined with travel, and the next section overlaps travel for work with travel for leisure. Like consumption at home, consumption at work reflects modern society. Even the more primitive cultures have access to some type of refrigeration and dehydration, making for a more varied working diet.

## Traveling

The earliest form of travel was by foot. The fare was simple, was carried in a knapsack, and was eaten on the trail. Hiking is no longer a necessity, but it is a popular activity throughout the world. The variety of edibles contained in the backpack would astound early travelers. Trail mix, a popular edible designed for eating while walking, has appeared on grocery shelves for general consumption. Overnight camping can be high tech and effortless, but many hikers prefer cooking over an open fire for taste, smell, and aesthetics.

The modern automobile comes equipped with holders designed to facilitate consumption. Many workers carry a travel mug containing their hot or cold beverage of choice in the car for consumption on the way to work. Those who choose not to brew at home find convenient drive-ins featuring breakfasts and hot beverages. This continues through the day and evening as drive-ins and restaurants compete for automobile or roadside diners. Travelers by car have a food treat not afforded other modes, the roadside fruit and vegetable stand. Travelers may stop at the side of the road and enjoy the fruit or juice of the region. Eating in the car has become so common that Americans have developed a slogan, "Friends don't let friends eat and drive." The campaign is not likely to be effective because around the world the automobile is an exceedingly popular place of consumption.

Travel by air has prompted two places of consumption, the airport and the airplane. Airplane travelers expect food on long flights, although expectations are not high, even in first class. Perhaps because of the reputation of airplane fare, many passengers eat before boarding or buy food at the airport to eat in flight. Airports often feature regional cuisine that offers the traveler one last chance to enjoy a local dish, albeit an expensive one.

One of the lures to travel by train was the dining car. Trains around the world offered white tablecloths and the appearance of fine dining. While a few specialty routes offered fine fare and required passengers to dress accordingly, on most twenty-first century trains clothing is casual, and food is adequate. It is usually the view passing the window that makes dining on the train memorable. Like the airport, the train station offers food for immediate consumption or for the trip. Prices are more reasonable than at most airports. The food is varied, and in some locations, such as Union Station in Washington, D.C., and Grand Central Station in New York City, the station is a destination for dining, not just travel.

Travel by water also provides eating opportunities. Whether by ferry or luxury liner, food is available en route. Ferries usually offer drinks and snacks. Hot beverages are especially appreciated in colder climates. Luxury liners offer fine cuisine with appropriate attire and manners. Most cruise ships offer opportunities for more casual dining too. Passengers wishing an informal trip by water choose a freighter, often by its reputation for providing tasty food. In the Western world, yachts and small

boats come with small kitchens. Eastern vessels may lack the kitchen but carry a small charcoal grill onboard. Traveling by sea seems to stimulate the appetite, even on the brief dinner cruise.

Whether traveling by foot, air, train, or boat, the modern traveler expects food and gets it. Of the four the traveler by boat is probably the best fed. Each mode may offer a splendid vista to gaze upon while consuming food. Of all the food consumers, travelers have the most exotic places of consumption.

## Playing

All work and no play is an old adage. Since the beginning of recorded history, the consumption of food has been an important component of play. This section features the variety of places where people eat and play, starting with some of the older pastimes still popular in the twenty-first century.

Fairs began as an annual event to celebrate the foods, crafts, entertainment, athletic prowess, and livestock of a given locale. Fairs have expanded to encompass states, countries, and the world. Food, such as candied apples and cotton candy, and the smells of barnyards and sawdust floors are unforgettable memories of many fairgoers. Fairs are not dress-up occasions in part because they are usually outdoor events held in temporary structures and tents.

The circus and later the carnival grew out of the fair. Both were situated out of doors and provided food for participants, notably popcorn, peanuts in the shell, and caramel corn. Today, there are fewer carnivals, and circuses have moved indoors. They have largely been replaced by television and theme parks. One outgrowth of the circus that seems here to stay and is found worldwide is the food circus, a grouping of food stalls featuring foods from around the world that can be enjoyed indoors and outdoors from Seattle to Singapore.

Athletic prowess has been celebrated by itself, as the long history of the Olympic Games testifies. Sports stadiums and arenas are traditional sites for food consumption. Baseball celebrates its memorable edibles—peanuts and cracker jack—in song. These staples have expanded to include hot dogs with mustard and sauerkraut and regional favorites such as tacos in the West and saimin in Hawaii. Other team competitions, such as football and soccer, include a variety of hearty snacks, regional treats, and lots of beer. The tailgate party precedes football games across the United States. With a distinctive regional flavor, food is often prepared adjacent to the car in the parking lot over hot coals and is shared with other sports enthusiasts. The lazy tailgater can find tailgate fare to go in the city.

The younger set also enjoys eating at the sites of their baseball, football, or soccer games. They do not provide the food, their parents do. More often than not the parents arrange a potluck. That way each family contributes,

Dining in shaded pavilions by cool pools of water has been a recurring theme in the history of Middle Eastern eating habits. This inviting enclosure is located at the Palace of Nerenjestan in Iran. © CORBIS.

and all share in the bounty. Athletic events seem to increase appetites and expand the places of consumption.

The street vendor has always existed around the world, in industrialized and developing countries. The food on each cart is limited, regional, and usually cooked at the site, and in underdeveloped countries it is often of questionable sanitation. For the brave the taste is delicious, but the suffering afterward may be keen. Tourist destinations, such as temples, museums, and historic sites, often offer an edible specialty of the area. It may have begun with priests and monks preparing food for the weary travelers. However, modern tourists expect to be able to purchase a drink or a snack upon reaching their destinations. If there is a specialty item to eat, some find it as exciting as the monument.

Natural beauty attracts visitors. Mountains, ocean beaches, deserts, lakes, and nature's curiosities draw crowds. With the crowds, opportunities to eat appear. When the sites are made into national or state parks,

some aesthetic control is established. If not, places of consumption can be unattractive to the eye and to the palate as well as a distraction from the beautiful scenery.

The movie theater has carried on the popcorn tradition. Popcorn and soda are musts for most moviegoers. Twenty-first century theaters, like cars, provide holders for drinks. Theaters must be swept after performances to remove the litter caused by moviegoers eating in the dark.

Walt Disney created the theme park, and with its advent came new places of consumption. Within the theme park are restaurants, fast-food facilities, and vendors. As theme parks developed into adventure parks, the places of consumption continued to grow.

Many enjoy an opera, concert, or play. Unlike their neighbors at the movies or athletic events, they cannot eat during the production. They are offered an intermission, when wine, beer, or snacks may be purchased, but they must not be taken back into the theater or concert hall.

For many throughout the world, shopping is an enjoyable leisure-time activity, of which food is an important part. Shopping malls are replete with food to be eaten seated or while walking. Shopping centers offer family-style restaurants and fast food. Department stores often devote a floor to eating establishments. While grocery stores may offer free promotional samples, large wholesale food chains offer so many samples that customers can and do make a meal of the shopping expedition. Little doubt exists that eating and playing go hand in hand around the world.

## Dining Out

The consumption of food in the home is more traditional in less-advanced societies, but highly technological societies have a vast array of dining-out opportunities and increasingly take advantage of them. This section introduces the myriad possibilities. The discussion is arranged from the most formal dining to the least and concludes with some special sites where food is consumed.

The finest dining, measured by expense and formality, usually occurs in large cities around the world. Such locations have dress codes that require men to wear suits or sport coats and ties. Women are monitored as well but, because of the nature of female attire, not as closely. In the most exclusive establishments, one must be appropriately attired to dine. Expensive but less-exclusive places offer men a "house" sport coat or tie. The emphasis on fine clothing is matched by the dress of and attention provided by the entire house staff, the quality of the china and tableware, the reputation of the chef, and most importantly the cuisine.

To afford the ultimate in exclusivity, private dining clubs are located around the world in major cities. Traditionally these were for men only. While this is no longer the case in the United States due to sexual dis-

crimination laws, it remains a phenomenon elsewhere around the world. Private dining clubs are often affiliated with a leisure pastime, such as tennis, golf, or yachting. Patrons of these clubs usually have dining areas where they may eat in the attire of the sport. However, on special evenings the dress code can be formal. In private clubs the places of consumption are attractive to the eye, are furnished with style, and offer a view if possible. Interestingly, the restaurant with the finest view seldom serves the finest food. Nonetheless fine dining usually means the finest money can buy.

The moderately priced restaurant is found worldwide. In the United States it is often a franchise with set menus and standardized ingredients. Whether serving families or corporately owned businesses, medium-priced restaurants are found wherever people congregate or travel. They offer food of the region and food from locations far away. In the United States the foods of China, Mexico, Italy, Thailand, and Vietnam abound. In fact, Chinese food or something resembling it is available throughout the world.

Dress codes are not restricted to fine dining establishments. Medium-priced restaurants in beach locations often require a shirt and footwear other than rubber sandals. Shorts may be banned for both sexes. These restaurant owners obviously believe that the attire of the patrons is part of the ambience of their places of business.

Outdoor dining is not as commonplace in the United States as it is in Europe and many countries in Asia. These establishments, called cafés, are generally located along city streets and offer dining inside and out. Coffee is always on the menu, and a cup of it alone can offer the patron an hour or two of street watching.

Specialty coffee shops serving latte, espresso, and cappuccino are popular places of consumption worldwide. Students study in them, senior citizens visit in them, and professionals dash in and out for a caffeine hit. The cost of both the coffee and the food sold therein is anything but cheap.

Around the world, bars and pubs (the word “tavern” is disappearing) are places to drink, to eat, and to congregate with friends. For many the neighborhood bar is a home away from home. While classic food items like pigs’ feet and hard-boiled eggs may still be offered, hearty sandwiches and salty snacks are the norm. Visiting the sports bar with its wide-screen television is almost as good as going to the game itself. Some would argue that it is better.

In the technologically advanced twenty-first century people are in a hurry. Food is often eaten on the run. As a result, fast food eateries have flourished, especially in the United States, in every city, town, and village and along most highways. They are apt to be franchised with standard fare. Patrons may eat inside in clean, colorful, sparse, and plastic surroundings or, more the norm, may take their food home, to another site, or consume it in

the car. The items most frequently offered include hamburgers, hot dogs, fried chicken, and a standardized version of Mexican food.

The drive-in restaurant appeared in the 1950s in the United States and afforded Americans a place to be waited on and to eat in the car. This novelty, just like the drive-in movie, has worn off and almost disappeared. It has been replaced by the drive-thru. The drive-thru offers fast food and is most often found in conjunction with a fast-food restaurant. However, depending on the part of the country, it may offer specialty items. In the Pacific Northwest, for example, the drive-thru latte abounds.

Caterers allow people to consume food in many locations where food is not prepared. Some examples are botanical gardens, meeting halls, aquariums, and outdoor sites. Many occasions, such as birthdays, anniversaries, showers, graduations, weddings, awards banquets, and even funerals, are celebrated with food. While they may be held in restaurants, many are catered in a variety of locales.

Whether dining in an automobile, a bar, or a bed, people around the world consume food several times a day. They appear to be limited in location only by their imaginations and the availability of food. Seldom does either limitation present a barrier to the consumer in the twenty-first century.

**PLATINA.** A noted humanist of the Italian Renaissance, Platina, born Bartolomeo Sacchi (1421–1481), is distinguished for culinary historians as the author of the first work on cookery ever printed: *De honesta voluptate et valetudine*, first in Rome c. 1470, without printer or date, then in Venice in 1475. Translation of the Latin title helps to define a central premise of the revolution in thought that broke with medieval traditions in fifteenth-century Italy. “On honest [meaning ‘legitimate’] pleasure and good health” speaks of Platina’s allegiance to new understanding and validation of the philosophy of Epicurus brought about from the 1430s by Lorenzo Valla, recognizing that rather than hedonism, it celebrated the creator’s love for humans in sensory endowments if these were enhanced through self-control and moderation.

In addition to an Epicurean orientation, Platina underscored his devotion to another Greek philosopher, Pythagoras, by signing the *i* in his name as the Pythagorean *Y*, symbolizing the divided path at which one must choose virtue over its alternative; the conceit appears also in the funerary inscription he designed for himself and his brother (Rome, S. Maria Maggiore). From Sacchi’s birthplace at Piadena near Cremona came his classicized name Platina, chosen in conformity with practice among fellow members of a premier Roman sodality of humanist scholars under the leadership of Pomponius Laetus, Platina’s friend and neighbor on the Quirinal, near the ruins of the Baths of Constantine. Reformist ideas gained from early Church fathers and from pagan antiquity that invested the self-styled “academy” of the Pomponians added to Platina’s problems in the curia of Pope Paul II. He was among those imprisoned and tried in 1468 for heresy, but shared in their return to favor under Sixtus IV from 1471. By 1475 Platina had been appointed chief administrator of the Vatican Library.

His treatise on cookery and good health seems to have been written and circulated in manuscript by 1465, following a summer spent with his patron, formerly his pupil in Mantua, the young Cardinal Francesco Gonzaga, as guests of the contemporary “Lucullus” of Rome Ludovico Scarampi Mezzarota, Cardinal Trevisan. The final six books of Platina’s study are Latin translations of recipes acknowledged as those of his friend, Maestro Martino of Como, head chef to Trevisan. Added to Platina’s advisories on principled well-being, essays on natural history, and Galenic medical lore inspired by humanist research in the writings of the ancient Roman agricultural writers, Pliny the elder, and Apicius (whom he calls “Caelius”), these final books or chapters enhanced the reputation of the work.

Platina/Martino remained in print until well into the seventeenth century, seeing Italian editions (often re-translating Martino’s vernacular text) in 1487 and 1494, a French translation in Lyons by 1505, and one in German by 1542, plus at least fourteen Latin editions. Abetted by pirated editions of Martino (whose manuscripts were not edited until modern times) such as Epulario (Venice 1516, said to be by one Roselli and very influential in translation for Tudor England) and another by Clement VII’s chef, Maestro Giovane, *Opera dignissima (et) utile per chi si diletta di cucinare* (A both elegant and practical guide to cooking; Milan, c. 1530), *De honesta voluptate* may be called the thinking man’s guide to Renaissance foodways, as opposed to representatives of a courtly tradition.

**PLEASURE AND FOOD.** The pleasure of food is the sensation of well-being that derives from the fulfillment of a natural instinct. Two essential elements are involved in food pleasure, the emotional and psychological tension created by the initial impulse or desire and the subsequent consummation of that inner need. Thus eating pleasure clearly corresponds with the two basic requirements of life, replication and sustenance.

Along the thresholds of pleasure, two distinct worlds intersect, the internal and the external. Pleasure from within is derived from a desire to satisfy the basic necessity of existence, while pleasure from without corresponds with the means of achieving that satisfaction. Both worlds are connected by the senses. Eating pleasure acquires enormous existential importance when confronted by the problem of the sensation or experience of living. This category of pleasure belongs to an area of the senses that is most basic and primal to the concept of happiness. In classical Greco-Roman culture it was consummated in

the Greek *symposion*, where primal pleasure was linked to a Platonic communication of ideas—in other words, the intersection of physical pleasure with spiritual pleasure. The biblical Book of Ecclesiastes also arrives at this conclusion, where the pleasure of feasting and the pleasure of friendship are found to be the only human alternatives to the vanity of existence.

The superiority of eating pleasure over all other forms of pleasure is obvious, for it is related to needs that are more long-term and vital, embracing the entire life span, from feeding at the mother's breast to the final moment of existence. In human beings the pleasant necessity of eating is renewed daily, and because it is ineludible, it also transcends any moral code. On the other hand, since the human animal is omnivorous, the sensory stimulation must be infinitely varied to accede to this kind of pleasurable experience. This same rationale collaborates with hedonism so fantasy can develop its maximum potential. From this comes the popular expression of “creating a need from pleasure,” which, when reworded in a more precise manner, ought to become “creating pleasure out of necessity.” Is this necessity a requirement for pleasure? Pleasure is one of the rewards for eating.

In the initial approach to the pleasure of food, the first signal comes in the impulse or need to eat. Later the bodily senses direct the person to a means for satisfying this impulse. Finally, distension is created in the act of eating itself. Yet culturally this simple phenomenon becomes more complex than that, since the stimulation deriving from food directly intervenes in the need to eat to the point of provoking it. Consequently the pleasure of eating has evolved into an art, the art of food consumption, with the goal to contain, draw out, and direct in a more focused and concentrated manner the primal necessity of nourishment. Unquestionably the need for satiety and for satisfying the senses plays a role in the pleasure of eating. Human and cultural contexts also add to this. Out of these conflicting sensations evolved the perceived ties between the pleasure of eating and the source of the food (such as climate and geography) as well as diverse cultural ideas defining it.

### **Pleasure and Culture**

Contrary to popular belief, the determining factor in the importance of food pleasure is not derived from the taste of foods produced in a given place but from their cultural contexts or definitions. For example, it is not the intense flavor of a homegrown orange that pleases, rather the idea that it is homegrown, which is a cultural value. Taste is chemical and biological; food pleasure is perceptual. Although pleasure derived from the act of eating is beyond question, its importance also competes with other forms of pleasure or other forms of interest current in a given social context. The availability of time, the relationship to other forms of pleasure, its ritualistic value, and its connection to health all help to define the hedonistic role.

Using Western civilization as a point of reference, the excess amount of food available creates a problem in selecting and determining the line of preparation a person should follow with any given choice, which is one reason for the proliferation of cookbooks. All of this may increase the pleasure of creativity in the kitchen but not the actual act of eating. Cultures in which the sources of nutrition are more limited exhibit a realization that consumption must take place as soon as time and circumstance will permit. Indeed in primitive cultures hunting, gathering, and eating all day long was a necessity. Thus in those cultures all the potential for pleasure was concentrated in the act of daily nourishment, even if it was just one meal from a common pot.

In non-Western societies the act of eating is sometimes occasional because of the sporadic nature of food gathering as well as the difficulty of conserving food in areas of high temperature and humidity. When the sources of food become secure and predictable, the food itself propitiates the ritualization of meals at fixed times. Mediterranean culture is paradigmatic in this regard, since daily, family-oriented meals take place at set times. These times are referred to as “sacred” because changing the fixed pattern would cause an imbalance within family relationships and personal well-being. The intimate relationship between pleasure and necessity makes it difficult to know to what extent pleasure affects such eating habits, since it is normal for pleasure to accommodate itself to all nutritional possibilities.

Appreciating the determinate element in pleasure requires an analysis of all gratuitous and extraordinary factors that intervene in the refinement and culinary expression of food. Unusual or complex methods of preparation not justified by any other reason, the inclusion of spices and additives that are purely hedonistic, extraordinary ingredients, and the presence of stimulating beverages, such as wine and liquor, are all elements clearly associated with food pleasure.

### **Cultural Differences**

The islands of Asia, especially Japan, have developed the visual elaboration of food to an art form. In continental cultures the importance of taste acquires greater emphasis. In the cultures of coastal regions with a mild climate, spices and herbs magnify the aroma of food. In the industrialized West closely managed food production and fixed times of consumption have altered pleasure with precooked or packaged meals. While this promotes growth for the food industry on a mass-market level, the elements of pleasure derived from the time devoted to preparation and consumption are diminished. Some examples of these elements are visual, as in Japanese dishes that resemble ikebana; intense flavor, as in the excessive heat in many tropical cookeries; the rich aromas of Mediterranean home cookery; and the infinite varieties of elaborate desserts available in all cultures. Yet food pleasure is mutable, and an inherent contradiction derives

The pleasures of tippling, heavy flirting, and good food are brought together in this memorable scene of a Twelfth Night feast painted about 1656 by Dutch artist Jacob Jordaens. © ARCHIVO ICONOGRAFICO, S.A./CORBIS.

from the fact that even microwave popcorn eaten in front of the television is pleasurable.

Each individual has his or her own pleasure values for food and alcohol, which for some is an actual addiction, such as chocolate, and for others a natural dimension of the extended food experience. The latter evolves into such things as wine as an aperitif before the meal, wine to embellish consommés, fish and meats, sparkling wines for celebrations, and sweet wines for dessert. Arguably wine is not necessary for food pleasure, for this is easily demonstrated in cultures that prohibit alcohol. The point, however, is that its pleasures are cultural, and where alcohol is perceived as part of the eating pleasure, it is employed to enhance it.

The evening meal has become by definition the most hedonistic, although the motives that give rise to this type of food pleasure may be quite diverse, such as business gatherings, a sentimental or romantic rendezvous, or celebrations and anniversaries. The classical symposium of

the ancient Greeks has been preempted by restaurants and hotels, especially those meals of a ritualistic nature. An example is wedding banquets, which are common and are becoming more and more similar the world over. To this can be added specific religious life-cycle observances, such as baptisms, communions, circumcisions, funerals, and the like. In the more industrialized countries the pleasures of food and eating have been banished to the position of last, behind such factors as dieting for better health or weight loss, fear of contaminants, and minimal time in preparation and consumption. Much of this has been defined by the various artificial "styles" of consumption created by the food-packaging industry in such labels as "home style" and "Oriental style."

### **The Ritualized Pleasures of Food**

Ritualized pleasure may be defined as the pleasure derived from the time designated for eating over the course of the day, and it varies greatly from one culture to the

next. In Europe it is defined by breakfast, dinner, and supper, to which some cultures also add optional meals in between. Two of these would be the light aperitif and the late afternoon break or snack. Both follow purely hedonistic impulses, both are defined by economic status, and both are limited by such considerations as care of children, the sick, the elderly, or workers who may require more nourishment due to hard labor. The aperitif has a more social and hedonistic quality since alcoholic beverages play an important role.

### The Pleasure of Beverages as Food

The problems alcoholic beverages pose derive from their double roles as mood-altering drugs and as hedonistic elements of food consumption. To begin with, the higher the alcoholic content, the more likely the beverage will be employed as a pleasurable drug rather than as an adjunct to food. Wine, with its infinite variations of aromas, tones, textures, and alcoholic content, is the beverage most used for pleasure at the table. Without a doubt it is also the beverage endowed with the most hedonistic associations, not to mention its intimate relationship with Judeo-Christian culture and Greco-Roman culture.

Liquors have a double origin in that they are often derivatives of other beverages of lesser alcoholic content, such as beer and wine. One of the major contributions of human ingenuity to the search for pleasure was the discovery that alcohol could be extracted from seemingly unlikely substances. Such is the case with liquors from cacti, milk, honey, seeds, or indeed any nutrient containing carbohydrates susceptible to alcoholic fermentation. These types of beverages with higher alcoholic content are the most distant from pleasures of the table because they are most like drugs, and many were in fact first employed as medicines. Wine alone is intimately associated with gastronomic culture.

### Pleasure for Pleasure's Sake

It has been said that the human being is the only animal capable of detaching itself from the pleasures of the natural instincts that sustain life. In the case of food, since it is connected to a vital necessity, expectation induces excitement. Pleasure, separated from necessity, is aimed more at taste than smell, more to the scarcity and cost of the food item, and more to the capacity for satiety, including the dimension of danger.

The history of elegant and refined food is written with rare and costly materials, which become the criteria for cultural values. The Romans prepared dishes appreciated because of their rarity, such as peacock eyes, which later seemed absurd and repugnant. Some foods that were once scarce and thus greatly valued subsequently were later viewed as vulgar because they were everywhere accessible. This commonness lessened the pleasure of their consumption due to the loss of their exotic and sumptuous qualities.

Finally, the ultimate forms of food pleasure come to the element of extreme danger. Mushrooms have always posed a great risk due to the possibility of poisoning, especially in earlier periods. This fear has not detracted from their gastronomic interest, rather, the risk has made them all the more attractive. Risk has achieved an even higher level of refinement in the consumption of fugu, a Japanese fish that poses sudden death due to the presence of dangerous toxins in its entrails. A dish composed of this particular species of fish and prepared by a specially certified chef is a luxurious delicacy in Japan, a pleasurable mockery of fear that can be experienced in the intense tingling the fish causes to the lips and mouth. Here the delicate meal passes beyond the boundaries of mere satisfaction. It is no longer food; it is a victory over death.

**POACHING.** The "moist heat" technique of poaching was very much a part of the recorded recipes of the ancient world. In one of the earliest cookbooks, the Roman Apicius's *De re Coquinaria*, recipes for delicacies like *Isicia Plena* (Dumplings of Pheasant) show that stiff forcemeat dumplings were poached in water seasoned with garum. And certain other savory and sweet recipes, like *Aliter Patina Versatilis* (A Nut Custard), instructed cooks to pour custard into molds to be placed into pans partially filled with hot water. After the invention of the printing press and the appearance of the first printed cookbook, *Le viandier* (1490), by the Frenchman Taillevent, the various aspects of poaching found a broader audience. However, it was not until the seventeenth

century and the ever-increasing management of fire that poaching as a culinary technique gained in popularity. In 1651, with the printing of original cookbooks in addition to the collected works of the past, recipes began to integrate a repertory of techniques, basic mixtures, and raw materials. Lightly cooking certain ingredients in a small amount of liquid was not only part of a process of making a certain dish, but it also opened the possibility of refining the dish with savory sauces.

When Charles Ranhofer, chef of the famous New York establishment Delmonico's, published *The Epicurean* in 1893, various poached egg, seafood, and chicken dishes were featured as sophisticated menu offerings. Ten years later in his monumental cookbook *Ma Cuisine*, Georges-Auguste Escoffier listed 141 variations for *oeufs pochés* along with fifteen more recipes for cold preparations including *en gelée* and *chaud froid* dishes. And when Prosper Montagné published *Larousse Gastronomique* in 1938, he provided the formulas for several poached egg dishes beginning with *oeufs Aladin* (poached eggs on a mound of saffron risotto, garnished with sweet peppers, and napped with tomato sauce) and ending with *oeufs à la zingara* (poached eggs placed on oval fried croutons covered with thin slices of ham, and coated with Zingara sauce, a tomato-flavored demi-glace with a julienne of ham, tongue, and mushrooms). The same sophistication in the utilization of poached fish and poultry could be seen in recipes for *filets de soles à la normande* and *suprêmes de volaille*. And with the advent of nouvelle cuisine and especially *cuisine minceur* (calorie-defused dishes developed by the French chef Michel Guerard) in the 1960s, poaching various ingredients in flavorful liquids and substituting innovative vegetable and herb purées for sauces canonized the technique of poaching as a healthy trend.

In comparing the various examples of "moist heat" cooking, the amount of liquid, the timing, and the temperature are distinguishing factors. In poaching, the item to be cooked is generally submerged entirely in liquid, except in shallow poaching, when the item is only partially submerged in liquid and loosely covered with parchment paper. Timing is critical and depends on the size, density, and ripeness of the item to be cooked. The temperature for poaching registers between 160° and 180°F (71–82°C), and should always be maintained lower than a simmer (185°F [85°C]) to guarantee tenderness.

Although plain water or salt and vinegar-infused water is used in poaching, the liquids more frequently utilized in this cooking method are usually more flavorful. Stock, court bouillon, vegetable juice, vermouth, and various aromatics, such as herbs, spices, and citrus zest, contribute to the taste of the item cooked and also serve as the basis for a congenial sauce to nap the prepared poached fish, poultry, vegetable, fruit, or meat.

Unlike boiling, which requires only water, a pottery or metal pot, and heat to perform, poaching has acquired through the years a distinctive *batterie de cuisine*. An ob-

long covered pan called a poacher with handles at both ends and a convenient rack for lifting the prepared item from the pan greatly facilitates cooking a large fish. Egg poachers feature an insert with a specified number of round or oval, often perforated, cups to submerge eggs in a pan of water. Also used are metal rings that contain the entire egg when it is slipped into the water. A specific kind of shallow skillet with sloping sides called a *sauteuse* is used for poaching smaller items. And to insure even cooking and avoid curdling, various custards, timbales, and terrines are poached in their containers in a bain-marie, or water bath.

### Poached Eggs

Instructions for poaching eggs are varied, many, and often contradictory. Some directions, for instance, recommend adding salt or vinegar to the poaching water; some call for breaking eggs into a saucer before lowering into the water; others for boiling eggs in the shell for ten seconds before breaking and poaching in water; still others for creating a whirlpool in the center of the pan and dropping each egg into it individually; and others for removing eggs and trimming them to the desired oval shape before serving.

The use of salt is debatable, although some chefs suggest that it speeds up the cooking process. Vinegar and acids, like lemon juice and wine, denature the proteins in egg whites and should be added to the poaching water. Breaking the egg into and as close to the poaching water as possible is the direct approach, but some cooks prefer the perforated cup method. Without exception, however, recipes for poached eggs advocate the use of the freshest eggs possible because the yolk membrane will still be strong, and the egg white will cling firmly to the yolk in a mass and not trail off in feathers. The older the egg, the looser the white becomes. Timing in poaching depends on the size and grade (Grade AA is preferable) of the egg, and the temperature of the poaching liquid. Some cooks suggest immersing in lightly boiling water and then, when the whites begin to set, reducing the water temperature to 175°F (79°C) or covering the pan and removing it from the heat. Cooking for too long a period of time, or with too hot a temperature, toughens the proteins. So attention to cooking time and water temperature is necessary, especially if the eggs are to be stored in fresh cold water for use later.

Recipes for poached eggs appear in almost every cookbook either as comforting food *pour un malade*, a display of the skill and inventiveness of the cook, or a staple of the breakfast/brunch buffet. Many distinctive dishes also are garnished with a poached egg, including the traditional veal cutlet dish Wiener schnitzel; the famous curly endive and lardon salad of Lyon, France; the American breakfast steak; and corned beef hash. In 1861, the Englishwoman Isabella Beeton suggested serving poached eggs on toasted bread or on slices of ham or bacon in her *Book of Household Management*. A hundred years

later, avoiding what she called “that sodden toast,” in *French Country Cooking* (1959), Elizabeth David recommended serving a poached egg on a purée of split peas, corn, or mushrooms, with fried bread on the side. And she included a traditional recipe for *oeufs Benedictine*, in which poached eggs are placed on a bed of creamed salt cod in individual flat dishes and napped with Hollandaise sauce. In *Simple French Food* (1975), an avid American practitioner of French cooking, Richard Olney, recommends preparing poached eggs and placing them in artichoke bottoms, topped with Mornay (cheese) sauce and surrounded by a julienne of lightly blanched vegetables (p. 101).

In the United States, serving poached eggs on a piece of toast covered with a slice of ham and napped with Hollandaise sauce translated into an American idiom when it was named after a Wall Street stockbroker (the term appeared in print for the first time in 1928). Lemuel Benedict reputedly used poached eggs, toast, and bacon sauced in Hollandaise as a cure for the extravagances of the “night before.” In time Oscar Tschirky, maître d’hôtel of the Waldorf-Astoria hotel in New York, refined the dish by substituting toasted English muffins and ham for the toast and bacon, and by adding shaved truffles. Eggs Benedict was also served at Delmonico’s restaurant in New York. The dish has not gone out of favor, but has been enhanced by many variations on the basic theme of a poached egg, toast, ham, and sauce blanche.

From the breakfast and brunch table to the buffet, chefs have devised multiple variations of *oeufs-en-gelée*, or cold poached eggs in jelly. Time-consuming but easy to make, jellied consommé or aspic is systematically added to a mold holding a poached egg and various garnishes until the mold is filled. After the final setting of the jelly, it is unmolded, and served.

### Poached Seafood

Poaching is an ideal way to cook a large fish because no fat is used. The skin can be easily removed, and the delicate flavor and texture of the fish is preserved. The cooking process begins in cold liquid, usually a court bouillon (vegetable broth and wine) and is maintained at 176°F (80°C). If a fish poacher is too large, small whole fish, fillets, and steaks are usually wrapped in cheesecloth for easy removal and poached in any pan large enough to hold sufficient liquid to cover the fish. Some cookbooks also suggest poaching delicate fillets in melted butter in an enclosed casserole, but rather than poaching, the French call this technique *poêler*.

Because the poaching liquid is both flavorful and acidic, reduction and emulsified sauces can be made to nap the fish, however, the glories of French cuisine have been more traditionally displayed in the repertory of elaborate sauces—Blanche, Bordelaise, Diplomat, Dauphin, and Hollandaise—frequently prescribed for fish.

Delicate shellfish like scallops, oysters, and shrimp can also be poached in wine, aromatics, or in their own

liquor. And seafood mousses in various-sized porcelain molds are always poached either on top of the stove or in the oven in a pan half-filled with water at 176°F (80°C).

### Poached Meats and Poultry

Almost any tender cut of meat or poultry can be poached, and this technique offers an alternative to meats whose exteriors are browned and caramelized in the cooking process. Sweetbreads, eye of the round, small legs of lamb, duck and chicken breasts, and even beef tenderloins can be poached in stock, with or without vegetables, in a comparatively short time, and either served hot with a variety of sauces or served cold encased in a flavorful jelly or *chaud-froid* preparation. (*Chaud-froid*, literally “hot-cold,” is a seasoned white or brown sauce to which gelatin is added; it is then spooned over fish or meat and glazed with aspic.) *Boeuf à la ficelle* is a classic variation on the traditional pot-au-feu, in which the beef tenderloin is tied with a string for easy removal from the poaching pan and served with vegetables and a reduction of the cooking stock. Formulas for finishing poached chicken breasts are as varied as the sauce repertoire for fish fillets, and again feature main course entrees as well as cold preparations.

A galantine is a dish made from the ground meat or forcemeat of poultry or meat that is stuffed into the skin of the chicken or duck of which it is made. Frequently the forcemeat is garnished with small cubes of ham, tongue, truffles, or pistachios. It is usually shaped into a cylindrical shape, wrapped in cheesecloth, tied with string, and poached in 176°F (80°C) liquid until an internal temperature of 160°F (77°C) is reached. When cool, the galantine is usually coated with aspic or a *chaud-froid* preparation.

### Timbales, Terrines, and Quenelles

A large timbale (Arabic *thabal*, drum) is basically a preparation of forcemeat, meat, fish, or fruit baked with eggs and seasonings in a crust in a round mold with high sides. Small timbales are single servings of custards with forcemeat, shellfish, fish, puréed vegetables and fruits made in glass or porcelain round molds instead of a crust and poached in a water bath of 176°F (80°C) in a warm oven. Nouvelle cuisine, especially, espoused a variety of flavorful puréed vegetable timbales which captured the essence of the flavor of the main ingredient.

Whether a terrine is made with well-seasoned goose, duck, rabbit, venison, pork, or liver combined with forcemeat or delicate shellfish, fish, and vegetable mousse, the rectangular mold in which it is baked in the oven should be standing in a water bath whose temperature does not rise above 176°F (80°C). It is the gentle poaching that distinguishes the terrine from the pâté, which is baked in a crust in a hot oven.

Quenelles, on the other hand, are meat or fish forcemeat dumplings that are bound with eggs, either piped or shaped into their distinctive oval shape with two

spoons, and poached in lightly salted water. Small shaped quenelles are often used as elements in various garnishes, such as *financière* and Toulouse. Larger quenelles, usually containing truffles, are used to embellish sizeable whole fish and other entrée presentations.

### Poached Fruits

Although many nutritionists maintain that eating fruits raw provides the most vitamins, many out-of-season fruits or slightly under-ripe fruits can benefit from light cooking or poaching in a sugar syrup variously flavored with a cinnamon stick, cloves, orange, lemon zest, or vanilla. Cooking with the proper proportions of water and sugar firms the fruit, and when the fruit is lightly cooked and removed from the liquid, the fruit syrup can be reduced and thickened. At that point, fruit liquors, brandy, or rum can be added to the fruit sauce to reduce the sweetness and add more flavor. Fruits prepared this way make for simple but elegant desserts; however, poached fruits can also be glazed and served on meringues or cookies, or in custards or fruit tarts and compotes as in the classic Peach Melba and Pears Belle Hélène.

As a cooking technique that is almost ten thousand years old, poaching has always had a certain culinary cachet. Associated more often with feasting than with famine, the process of gently cooking delicate marrows, fish, shellfish, eggs, fruits, and certain kinds of poultry and meats in savory liquids has always lent finesse to various dishes, while, at the same time, exhibiting the skill of the cook.

**POISONING.** Throughout history and across cultures food and drink have been used to deliver lethal poison. Since a person's demise from a slow-acting poison mimics so many natural diseases, and there is typically a time lapse between administration and expiration, this method made it almost impossible in early times to prove homicide. With the advent of chemical analyses for poisons (rudimentary arsenic tests were introduced in the 1840s) and autopsy, poisoning in the early twenty-first century, if suspected, is readily detected.

### Poisoning in History

Since at least Greek and Roman times, there is historical documentation of poisonings. During the reign of Artaxerxes II of Persia (405–359 B.C.E.), it was said that his queen, Parsysatis, poisoned her daughter-in-law, Satira, by serving slices of fowl carved with a knife that had been coated on one side with venom. This allowed the queen to dine with Satira—Parsysatis reserving for herself the uncontaminated slices.

When selecting food or wine to serve as vehicles for poison, poisoners prefer a substance that will mask the bitter taste of the poison. Consequently, sweet foods were often selected. Wine had the advantage of preventing the victim from being on guard. Tea, coffee, hot chocolate, tarts (sweet and savory), jams, puddings, fruit pies, pastries, steak and kidney pie, chocolates, corned beef, porridge, and rice have all been used in poisonings.

According to medieval literature, many prelates, sovereigns, and pretenders or heirs to the throne were victims of poisoning plots. The murderers were most often from the victim's inner circle. In 1152, for example, Hugues d'Amboise was poisoned by a coterie of his knights at a banquet given by his brother. The historical heyday for poisonings was Renaissance Italy (1400–1700). So many deaths occurred that Romans hardly believed that any man of prominence or wealth had died a natural death. The legendary Borgia family, specifically Lucretia, gained a wide reputation for poisonings, especially of cardinals. Cantarella, a slow-acting poison, was said to have been dropped into food or drink, even sacramental wine. These murders were supposedly undertaken on behalf of Lucretia's father, Pope Alexander VI, who as head of the Roman Catholic Church was heir to the cardinals' estates. As these allegations were repeated, they became part of the historical record. More recently, they been revealed to be outright myth.

## ROYAL TASTERS

During the Middle Ages and Renaissance, fear of poisoning was so great that royalty required that their food and drink to be tasted in their presence before they would eat. The tasting—a complex ceremony—usually fell to the food-preparers and servers. For Charles the Bold, Duke of Burgundy from 1467 to 1477, for example, the kitchen steward first tasted all food under the watchful eyes of the house steward. Then, as each dish was uncovered before the duke, a sample was given to official plate-bearer for tasting. The butler was the last servant to taste the dishes.

Wine required its own ritual. The royal cupbearer poured the libation into not only the duke's glass but into a tumbler as well. The glass was immediately covered, and water was added to the tumbler, which was drunk by the cupbearer's assistant. Only then would the wineglass be placed in front of the duke.

Tasting practices were largely abandoned in the mid-sixteenth century, although the ceremony was retained until the seventeenth century. Tasting is still practiced in the early twenty-first century in some Middle Eastern countries and Thailand.

In some form, tasting rituals have been with us since hunter-gatherer days when it was by trial and error that our ancestors learned to distinguish toxic from nontoxic plants. In the 1990s, research on taste has identified a subset of people known as supertasters, most often female, who have the genetic ability to sense tastes more intensely. They are so supersensitive to bitter tastes (a characteristic of poison) that the flavor actually causes them pain.

Throughout the literature, there are numerous examples of poisonings associated not only with women but also with their adultery, magic, and witchcraft. The near hysteria that swept nineteenth-century Victorian England, generated by tabloid reports of trials of forty women for putting arsenic in their husbands' food, was misplaced paranoia. When death records were examined, it was found that spousal murder of all kinds had risen dramatically between 1830 and 1900, with about one thousand people being found guilty. More than 90 percent of these murders were committed by men, the result of beatings and stabbings; only twenty cases were poisonings of wives by husbands.

In the twentieth century, concerns about poisoning of both food and water came to focus on bioterrorism.

There are other instances in which an assumed poisoning has profound historical implications. When the exiled Napoleon Bonaparte died in 1821, his demise was at first attributed to stomach cancer, but examination of his hair has found the presence of arsenic. In the 1960s, the U.S. Central Intelligence Agency (CIA) devised a number of food- and drink-based poisons for assassination, including a lethal milkshake intended for Cuban leader Fidel Castro. Ultimately, the spy agency abandoned this, as the delivery system was too unreliable; it was thought to be much easier to get a target to inhale poisonous gas. In his 1962 autobiography, the late King Hussein I of Jordan relates his uncovering of a Syrian Intelligence plot to bribe his cook to poison his food. The tip-off: The untimely deaths of the palace cats, victims of the assassin's experiments.

### Poisoning in Fiction

Poisonings have become the stuff of myth and legend, and a staple of mystery writers. The premeditation of the crime—acquisition of poison, calculation of lethal dosage, decision about which food or drink to use, preparation of the concoction, and making the victim consume it—adds to the insidiousness of the murder. In the fairy tale *Snow White*, a story that has survived for centuries in all European countries and languages, the wicked queen offers Snow White a poisoned apple that will induce a deathlike coma. The duel scene in Shakespeare's *Hamlet* features a poisoned cup of wine intended for the prince but mistakenly and fatally drunk by his mother, Queen Gertrude. In the 1941 American play "Arsenic and Old Lace," two seemingly innocent sisters in their sixties poison twelve men (a thirteenth as the curtain falls) with their homemade, arsenic-laced elderberry wine. In the 1996 literary mystery bestseller *The Debt to Pleasure* by John Lancaster, gourmet murderer Tarquin Winot suffers a brief setback when his intended victim turns down one of Winot's famous mushroom (Death Cap) omelets, saying he is allergic to eggs. After arguing that migraine is a small price to pay for gustatory pleasure, Winot recoups and whips up mushrooms on toast. In this poisoning, the food is not simply a disguise for poison, but the poison itself.

### Gender and Poisoning

Although poisonings are committed by both men and women, they have been stereotyped as a female crime. In 1584, English writer Reginald Scot claimed women had invented poisoning and were "addicted" to the method. Nineteenth-century European writers, including criminologists, always profiled the poisoner as female. As recently as 1961, criminologist Otto Pollak claimed in *The Criminality of Women* that poison was the murder method of choice of most female offenders. Women's social roles as wives, meal-preparers, and caretakers, he argued, afford them unique opportunities to commit poisonings.

In a celebrated case in 1984 in The Dalles, Oregon, members of a religious cult inserted salmonella bacteria in salad-bar foods, provoking 751 cases of infection. The purpose (this was only a trial run) was to keep voters away from the polls in an election several weeks hence where a land-use issue involving the cult's property could have an unfavorable outcome. Intentional criminal poisoning was not suspected at first; it was proved a year later. A paper written on the case was not published until 1997 out of fear of stimulating "copy-cat" incidents. Two other cases in Asia in 1996 include a mass poisoning with cyanide inserted into a curry stew at a festival in Japan, killing four people and, in India, the contamination of rice at a canteen with datura, a poisonous weed of the nightshade family, causing fifty-two fatalities. In the wake of the terrorist attacks in New York and Washington in 2001, the possibility of intentional poisoning of the food and/or water supply is being taken very seriously, particularly where botulinum toxin, the most deadly chemical known, is concerned. Where heads of state and other dignitaries are concerned, this has translated into extensive background checks on food preparers, servers, and suppliers as well as x-raying of liquor and produce received by restaurants and close surveillance in the kitchen.

**POLITICAL ECONOMY OF FOOD.** In the eighteenth and nineteenth centuries the term "political economy" referred to concerns classified under the discipline of economics. In the twentieth century Marxist

and Social Democratic critics of the emergent discipline, who believed it was blind to systematic social inequalities, primarily used the term. In the twenty-first century inequality, both national and international, continued as the hallmark of any work identified with the tradition of political economy.

Three kinds of work typically are classified under the rubric of political economy of food. The most widely recognized is political economy of hunger, especially the work of the Nobel laureate Amartya Sen. A second group concentrates on food fights between great powers, such as the conflicts between Japan and the United States over rice imports into Japan. The third group focuses on the development of underdevelopment, that is, processes by which poor nations are kept poor.

#### Political Economy of Famines

Sen and his associates developed a richly empirical research agenda showing that famines occur not because of too many mouths to feed but because the poor cannot access food. Famines in the late twentieth century occurred in sparsely populated regions, such as sub-Saharan Africa, not in densely populated China, India, or Bangladesh. Although populations continued to grow dramatically in India and Bangladesh, those nations last experienced famines in 1947 and 1974 respectively, the dates they became independent. This implies that where political will exists famines can be averted by following "famine codes." Developed in British India in the 1880s, famine codes are both early warning systems and suggested countermeasures, such as wage employment in public works. Famine codes are only effective in the presence of a relatively coherent public administration and transportation and communication infrastructures. Ethiopia, Somalia, and Afghanistan lacked these elements. The last catastrophic famine in China, which probably killed about 20 million people between 1959 and 1961, occurred in the context of a disintegrating communication system within the Chinese Communist Party.

Why repeated famines in sub-Saharan Africa? The immediate problems of eastern sub-Saharan Africa are civil war and the dispersal of the rural population, which is 18 persons per square kilometer (8 for Somalia), compared to 228 for India, 681 for Bangladesh, and 104 for Nigeria. In a dispersed population the transportation system is underdeveloped and cannot support relief efforts. Dispersed settlements also provide little scope for building efficiencies in terms of the social division of labor and market development. Furthermore in much of this part of Africa the primary form of agriculture is slash-and-burn cultivation, which is a fragile system of sustenance in the first place. Yet such an extensive approach is essential to survival on land of some of the poorest quality anywhere in the world. On the African continent 60 percent of the area has a high expectation of drought, and only 30 percent of the land is suited to rain-fed production of millet, sorghum, and maize (Drèze et al., 1995).

Much of the potentially good land is exposed to endemic sleeping sickness that affects both livestock and humans.

Most people starve because they are either unemployed or the price of the agricultural commodity they sell is so low they cannot afford enough food in exchange. If the latter is the cause, as in most of sub-Saharan Africa, producing more cheap food in the first world for export to the poor nations drives down prices further and creates more misery.

### Food Fights

Geopolitics have been central to the highly visible food fights between the affluent nations of the European Union, the United States, and Japan. In the 1940s the United States and the European nations assumed that agriculture would be relatively protected for reasons of reconstruction following World War II. But once Western European farmers revived, the U.S. government defended its share of the domestic agricultural market with the 1952 Defense Production Act, which banned the importation of anything from Danish cheese to Turkish sultana raisins (Friedmann, 1993). By 1975, when the European community had become a net exporter of wheat, the transatlantic trade conflict had become significantly hotter. In 1992 the Common Agricultural Policy of the European Union introduced support for domestic oilseed production and brought the transatlantic cousins to the brink of a trade war. Subsequently the most visible fights centered on hormone-injected beef and bananas.

Similarly during the military occupation of Japan, the United States sought to create a social base for the democratic system it was seeking to impose. The United States allowed Japanese protection of farm incomes both for the sake of recovery and in the interest of strengthening Japanese democracy. However, once the Japanese economy was independent it inevitably generated a conflict with the United States over markets and farm subsidies. This time instead of centering on wheat, maize, dairy products, and soybeans as with Europe, the conflict concerned rice, citrus, beef, and soybeans. Eventually the parties compromised on Japanese national sufficiency in rice and dependence on the United States for soybeans, nonrice grains, and beef. Protected rice remained an irritant in U.S.–Japanese relations in the twenty-first century.

### Development of Underdevelopment

Political economists of underdevelopment concentrate on a segment of the international trade in food products that is distorted to benefit first world nations. Their basic argument is that free trade in food products never has existed. The U.S. government, among the most ideologically committed proponents of free trade, paid American farmers \$71.5 billion in agricultural subsidies between 1996 and 2000. While pressuring third world nations to remove subsidies to their farmers, the first world nations heavily subsidize their capital-intensive agricultural sys-

tems. International trade in agricultural produce is shaped not by comparative advantage but by comparative access to subsidies (Watkins, 1996). Highly subsidized first world agricultural surpluses have created a serious disincentive for poor farmers in the developing world.

Furthermore it is argued that these unfair trade practices serve the interests of large corporations in the first world, such as General Foods, as illustrated by the case of instant coffee, the penultimate product of a commodity chain that begins with green coffee beans. Coffee is grown mostly in third world countries and is consumed in the first world. Most value-added parts of roasting, grinding, and packaging are done in first world countries. At the end of World War II the market was dominated by first world corporations, but major producers of green coffee, such as Brazil, sought “forward integration,” from coffee to instant coffee, to appropriate more value-added parts of the chain. Brazilian prices were about 20 percent lower, and the quality of the powder was higher (Talbot, 1997, p. 124). General Foods opposed Brazilian imports that cut into the company’s profits. The corporation lobbied hard for Article 44 of the Coffee Agreement, which compelled Brazil to impose an export tax on instant coffee and to sell 560,000 bags of green coffee beans per year to its competitors in the United States without the export tax. Receiving almost one-half of this coffee, which it converted to instant coffee, General Foods developed a further advantage over its Brazilian competitors by way of marketing and distribution networks.

In the larger pattern Mike Davis (2001) showed how colonial governments created the third world at the end of the nineteenth century through agricultural policies in the course of subsistence crises in 1876–1879, 1889–1891, and 1896–1902. These three crises were triggered by El Niño events, but capitalism had destroyed traditional networks of support, such as patron-client relations and their associated notions of customary charity, which resulted in the deaths of about 30 million people in the third world and generated conditions of chronic poverty. For example, Europe and India had relatively equal standards of living in 1800, but by 1900, Europe’s standard of living was about twenty-one times higher than that of India, by economist Romesh Chunder Dutt’s estimation based on the quality of housing, clothing, and diets (Davis, 2001, p. 292). By the end of the nineteenth century the processes of underdevelopment were firmly in place.

**POPCORN.** Popcorn was an early variety of maize, whose range in pre-Columbian times extended from the American Southwest to Chile. It was introduced into New England about 1800 and almost immediately became popular. Its main advantage was that, when heated, it exploded. While this trait is not unique, popcorn expands to a much greater extent than other varieties of maize and other seeds. This explosion fascinated children, and popcorn became increasingly associated with children and children's holidays, such as Halloween, Thanksgiving, Easter, and particularly Christmas, when it was given to children and employed as tree decorations. Popcorn was also used in children's confections such as popcorn balls, which were sold at circuses, baseball games, and fairs. Cracker Jack, a popcorn, peanut, and molasses combination, became the most famous confection in the world by the early twentieth century.

### Movie Popcorn

Until the 1930s, popcorn was not sold in movie theaters. To some owners, vending all concessions was an unnecessary nuisance because profits were negligible compared with the trouble and expense of cleaning up spilled popcorn and scattered boxes and sacks. Theater owners shifted their perspectives dramatically during the Depression, when popcorn's profit margin of almost 80 percent generated more income than did the box office sales.

During World War II, sugar and chocolate were rationed, and popcorn was the obvious alternative. Popcorn sales soared. By 1945, almost half of the popcorn grown in America was consumed in theaters. By 1949, surveys showed that 86 percent of the movie theaters in the United States sold popcorn, which six out of every ten patrons bought.

When television took America by storm in the 1950s, movie popcorn sales declined. Despite initial misgivings, however, the advent of television gave popcorn producers a boost unparalleled in their history. Americans who bought popcorn in movie theaters also wanted popcorn when watching television. The first product for the home market, "TV Time" popcorn, was unsuccessful. However, it triggered a convenience revolution in popcorn. Frederick Mennen experimented with an aluminum package to which he attached a wire handle. (Electric

Popcorn has become an icon food largely through its association with the cinema. It was one of the first foods to be served in movie theatres and remains one of the most popular of all foods eaten in theatres. © CORBIS.

poppers were manufactured shortly after the turn of the twentieth century. They did not become big sellers until major retail stores began offering them in their catalogs.) In October 1959 the newly created Mennen Food Products Company launched "Jiffy Pop." It was marketed as a fun food that youngsters could easily prepare and parents could conveniently tidy up, and a national advertising campaign made it an immediate sensation. In 1960 Jiffy Pop sales exploded. American Home Products acquired Jiffy Pop, which continued to sell well throughout the 1960s and into the 1970s.

### Microwave Popcorn

Percy Spencer of Raytheon discovered the heating properties of microwaves when he leaned in front of the microwave tube with a candy bar in his pocket—it promptly melted. He then popped corn using the microwave tube. Spencer's discovery led to the birth of microwave ovens. Spencer's first patent application for heating food with microwaves was submitted in 1945. However, the cost of the early microwave ovens was simply too high to justify buying one to pop corn.

During the 1960s, two major events turned the microwave oven industry around. The first was the invention of a compact, low-cost magnetron. The second was the invention of the self-stable microwave popcorn, “Micro-Pop,” which had a multilayered film package that kept moisture in and oxygen out. Today, the majority of popcorn consumed in America is popped in a microwave oven—its second major use in the United States.

### Orville Redenbacher

Before the 1950s, popcorn was sold at the regional level, rather than on a nationwide basis. It was considered a generic item, and quality was not a key factor in selling the product. It was promoted as an economical snack. High poppability of all the kernels in a package was the main claim advertised to consumers. Orville Redenbacher and Charles Bowman singlehandedly introduced the concept of “gourmet” popping corn, proving that consumers would pay more for a product that popped up “bigger, fluffier, and more tender.” At first, Redenbacher literally sold Red Bow out of the trunk of his car. He and Brown visited Gerson, Howe and Johnson, a public relations firm located in Chicago, who convinced them to change the name from Red Bow to “Orville Redenbacher’s Gourmet Popping Corn.” As the price was higher than that of other popcorn, the agency argued that consumers needed to be convinced that Redenbacher’s popcorn was of a better quality than its competitors. With virtually no advertising, they had achieved their success through word-of-mouth promotion. But Redenbacher and Bowman could not market their product nationally without additional assistance. In 1973 they teamed up with Blue Plate Foods, a subsidiary of Hunt-Wesson Foods based in Fullerton, California, to market their gourmet popcorn nationally. This connection permitted national advertising and a widespread distribution system. Appearing on numerous television shows as part of a massive advertising campaign, Redenbacher became a television personality. He made hundreds of personal presentations a year and appeared in scores of television commercials. Redenbacher was one of America’s most unlikely television stars. His bow tie, dark-framed spectacles, and Midwestern accent convinced many that he was just an old country hick. Consumers easily recognized the glass jar and simple label adorned with Redenbacher’s folksy image. It lent the product owned by a corporate giant a homey, small-town aura.

Popcorn represents less than 0.02 percent of the entire maize crop. Of all the types of maize, however, none is more commonly recognized than popcorn. Americans eat popcorn in movie theaters, amusement parks, and sports arenas, and around campfires. As a snack food, we feast on ready-to-eat savory and candied popcorn confections. American intake of popcorn in all forms has more than doubled during the past two decades, and consumption abroad has expanded at an even faster pace. As trivial as popcorn may appear when compared to the to-

tal maize crop, Americans annually devour 11 billion popped quarts, an average of about forty-four quarts per person. By volume, popcorn is America’s favorite snack food. And, partly aided by the spread of American popular culture overseas—including the export of American films—popcorn consumption has also increased in Europe and Asia.

**POPULATION AND DEMOGRAPHICS.** Every place in the world has a population, human or otherwise. Big or small, old or young, growing or declining, every population changes over time and space. Human populations inhabit countries, cities, suburbs, and rural areas. In some places populations are dense, in others sparse. In some places there are more young people, in others more old people. Men dominate in some places, women in others. All of these factors constantly change over time. The study of all the statistics that describe how populations change over time and space is termed “demography.” Demographic data includes, among other things, the size of a population, its density, spatial distribution, age, and gender.

### Population Distribution

The distribution of the world’s population is spatially uneven. Deserts contain very few people, for example, and cities contain many. Different countries, too, have very different populations. For example, consider the contrast between China and the United States. With a population of over one billion, China contains 21 percent of the world’s population, whereas the United States, with a population of 283 million, has less than 5 percent. The number of people per unit area of land—the population density—also varies among countries. In a small country like the United Kingdom (population 59 million), the density is 628 people per square mile. In comparison, a large country like the United States has a population density of 76 people per square mile, despite its larger population. Within countries, population densities vary significantly. São Paulo, Brazil, for example, has a density of around 17,000 people per square mile, whereas

Amazonia has one of the lowest population densities in the world.

Since birth and death rates change over time, and since people migrate from one place to another, the world's population distribution is always changing. Countries where birth rates are greater than death rates will, in the future, gain a greater share of the world's population, as compared to countries where birth rates are similar to or less than death rates. Cross-country migration is another important factor contributing to changes in population distribution. In the early twenty-first century, some 150 million people, or 2.5 percent of the world's population, migrated either temporarily or permanently away from their countries of origin. For example, due to high rates of immigration (mainly from Latin America), the foreign-born population of the United States increased from 9.6 million in 1970 to 24.4 million in 1998. People also move within countries from rural to urban areas in a process known as urbanization. In less developed countries, for example, urbanization takes place at a rapid rate: just 18 percent of people lived in urban areas in 1950, compared to 40 percent in 2002. This number was expected to reach 56 percent by 2030.

Populations are likewise characterized by age and gender distributions. Some countries have an overwhelmingly young population, most notably those in Latin America and Africa, while others have aging populations, such as the more industrialized countries of North America and Europe. Different populations also have different sex structures. Urban societies, for example, have more males than females, a higher proportion of young adults, and a greater life expectancy.

### World Population Growth

On a worldwide scale, population increases when births outnumber deaths. Although experts disagree on how exactly the world's population has grown over time, it is clear that for most of human history population growth proceeded at a very slow rate. Estimates suggest that in 40,000 B.C.E. the world's population was approximately 1.5 million, and it increased to 700 million by 1750. A falling death rate and a steady birth rate resulted in a marked increase of population to 1.6 billion in 1900. After this, in what is often termed the "population explosion," the world's population took an unprecedented move upward. In a mere sixty years the population almost doubled to 3 billion. Forty years later, in 2000, it had doubled again to over 6 billion. The reason for this growth was a rapidly falling death rate, a trend usually attributed to an increase in the world's food supply and a reduction in the rates of disease. Birth rates also fell, partially as a result of the spread of contraceptive practices, thus slowing the potential growth rate. The continuing decline of the birth rate means that the rate of population growth, though still rapid, has been slowing down. In 2002 the birth rate stood at around 1 percent, or 80 million more people per year.

### Population and Food Supply

To some, the growth of the world's population has been the cause of much alarm. Even though greater food availability is part of the explanation for the ever-increasing population, at one time it seemed unthinkable that the world could support so many people. The relationship between population growth and the human food supply has, in fact, been the subject of a heated debate for hundreds of years. On one side are the so-called neo-Malthusians, named for the English clergyman Thomas Malthus. In 1798 Malthus wrote the "Essay on the Principle of Population," in which he argued that population has a tendency to increase geometrically (or more appropriately stated, exponentially), but food production increases arithmetically. Thus, population will eventually outstrip food supply, the result being many deaths from starvation. Neo-Malthusians tend not to share Malthus's analysis in its entirety; they simply share his belief that it is possible to have too many people in the world. The world, in other words, can become "overpopulated" if the number of people exceeds a carrying capacity determined by food availability and environmental resources.

Modern-day neo-Malthusians—such as Lester R. Brown, Paul Ehrlich, Joel Cohen, Donella H. Meadows, Thomas F. Homer-Dixon, David Pimentel, and Norman Myers—believe that population growth is a cause of famine and environmental destruction. Growth, they argue, has limits. Generally speaking, they claim that the increased demand for food arising from population growth reduces agricultural resources per person, degrades the environmental conditions in which agriculture is practiced (via soil erosion and deforestation), and exacerbates macro-environmental change (such as global warming and the depletion of the ozone layer). These changes result in a decline of food production per person and, consequently, specific populations (especially those in poor countries) experience increased death rates from malnutrition. In his book *The Population Bomb*, Paul Ehrlich predicted that by the 1980s the world would see massive famines as a result of food shortages stemming from overpopulation. The much-discussed 1972 Club of Rome report "Limits to Growth" concluded that the world could not support economic and population growth indefinitely. Environmentalist Lester Brown argued in numerous texts, most notably 1994's *Full House*, that the demand for food leads to the adoption of more intensive agriculture, which degrades environmental resources and leads to a slowdown of food output. In *Environment, Scarcity, and Violence*, Thomas F. Homer-Dixon maintained that environmental resources are being degraded by rapid population growth, a situation he believed would lead to conflict and insurrection, particularly in the developing world.

On the other side of the population growth debate are those who are more optimistic about the growth of the world's population. Although they possess a wide variety of views, the so-called optimists look at the situa-

tion differently. Broadly speaking, they reject the concept of overpopulation and the notion that earth has a certain carrying capacity determined by food supply and environmental limits. Rather, the optimists believe that population and resources can be manipulated by humans through ingenuity and innovation and are therefore relative.

Some of Malthus's critics are termed "cornucopians" because they believe population pressure induces technological and institutional changes that can raise food output per person. Ester Boserup argued in *The Conditions for Agricultural Growth* that population growth stimulates improved methods of agricultural production—via crop rotation, fertilizers, and so on—thereby increasing food supply. The economist Julian L. Simon was another prominent cornucopian. In *The Ultimate Resource*, he reasoned that the demand for food influences the choice of agricultural technique and leads to adoptions of innovations in market agriculture. Simon also argued that a larger population also stimulates food availability, first by expanding the pool of inventive thinkers, thereby in-

creasing the propensity for technological change, and second by making effective food distribution systems more cost-effective. An example of technological change often put forward to disprove Malthus's thesis is the development of high-yielding varieties of crops such as rice. Bred as part of the "Green Revolution" in the 1960s, these kinds of crops arguably enabled India and other countries to feed themselves, thereby counteracting fears of calamitous starvation.

Other thinkers do not concur with Malthus simply because they believe that political and economic conditions, not population growth, determine famine and environmental destruction. An early critic of Malthus was the political economist and philosopher Karl Marx. In works like *Capital* (volume one), written in the 1860s, Marx accused Malthus of excusing the social conditions of his time, conditions that Marx believed were the real cause of poverty and hunger. The need to accumulate profit, Marx said, inherently means that at certain times there is a "relative surplus population," a labor force that is largely superfluous to the needs of industry. Thus,

FIGURE 1

there is a class of people who periodically are unable to earn enough to afford a means of subsistence. In this way Marx asserts that it is the economic system, not population growth, that creates a population in which too many people do not have enough to eat. Economics professor and Nobel Laureate Amartya Sen has also argued that poverty and famine cannot be blamed on overpopulation. Though he accepts that population growth can place undue pressure on the environment and the lives of women, in *Poverty and Famines* he argues that famine results from a collapse in people's ability to purchase or otherwise acquire food, not from a shortage of food. Another critic is advocate Frances Moore Lappé and her colleagues. In *World Hunger: Twelve Myths*, she noted that there is no correlation between population density and hunger, and that population growth is not the root cause of hunger but is itself a consequence of social inequality. The solution, she said, is to distribute more equally the world's resources.

### Trends in Population and Food Production

Throughout history, the world's food supply has grown faster than the world's population, as illustrated by the increase in the amount of cereals produced per capita. Figure 1 gives an example from recent history, indicat-

ing that cereal production has outstripped population growth since 1960 as a result of increasing yields. The area harvested per capita has actually declined.

Given this trend, it appears that neo-Malthusians have been overly pessimistic about the growing population. Most neo-Malthusians now accept that changing methods of food production have stimulated yield in a way not predicted by Malthus, but they claim the real problems have only just started. As evidence, they point to the declining rate of per-capita cereal production since 1985 (Figure 1) and the stark contrasts in food supply at the regional level (Figure 2). For example, cereal production is 0.125 metric tons per person in sub-Saharan Africa and has been declining over the past few decades. In South Asia, the per-capita rate of cereal production is higher, and the trend has been moving steadily upward. The developed world, as exemplified by the United States, produces far more cereals per capita (1.21 metric tons), but the amount has fallen since 1985.

Long-range future projections by the United Nations suggest the world's population will continue to grow, reaching 7.67 billion in 2020, and eventually 11 to 12 billion or higher by the end of the twenty-first century. Over 95 percent of growth will occur in the devel-

FIGURE 2

oping world, and the largest absolute and relative population increases will occur in Asia and Africa, respectively. Much of this growth will be in cities. The developing world's urban population is projected to double from the 1995 level of 1.7 billion to 3.4 billion in 2020.

This ever-growing population means an increased demand for food. Estimates of how much will be needed depend on the weight given to demographic factors, such as population growth, and nondemographic factors, like changing per-capita consumption. In an estimate by Tim Dyson in 1996, population growth alone will stimulate cereal demand by 728 million tons from 1990 to 2020; if nondemographic factors are accounted for, demand will be over 1 billion tons in total. Simulations by the International Food Policy Research Institute (IFPRI) predict that the world's population will demand 690 million tons more of cereal in 2020 compared with 1995. Eighty-five percent of the added demand will come from developing countries. The increasingly urbanized nature of the population means that the demand for meat will increase by 115 million tons.

The question of whether the food supply will keep up with the growing population is also the subject of a debate that has grown on local, regional, national scales. Concerns are greatest about developing countries. IFPRI predicts that food supply will not keep up with food demand in these countries. Yet IFPRI also points out that if cereal imports from the developed world doubled from 1995 levels to 2020, demands would be met. On the regional scale, sub-Saharan Africa has been the subject of significant attention. Issues such as drought and land degradation, warfare, and HIV/AIDS are all predicted to have an impact on the current trend toward declining per-capita food production. At the national scale there have been particularly marked debates about China. In *Who Will Feed China?* Lester R. Brown predicted that factors such as declining land availability and the degradation of water supplies will result in a shortfall of cereal production relative to population growth.

More recently, the debate has moved toward the community and household scale, the level at which people access and consume food. At this scale, however big or small the population, people are only able to eat enough food if they can access it. In order to do that, they need the means to grow food for themselves or, more likely, the money to buy it.

**PORK.** See **Mammals; Meat; Pig.**

**PORRIDGE.** Porridge is generally defined as a dish made by stirring oatmeal or rolled oats into boiling water and simmering the mixture gently until it is cooked. It is usually eaten hot; often, though not invariably, for breakfast. Meal or flour from other cereals may be used, in which case the dish is so designated; the cooking liquid may be water or milk or a mixture of both.

Porridge is considered an essentially Scottish foodstuff—it was hailed by Robert Burns, Scotland's national poet, as "The halesome parritch, chief o' Scotia's food"—even though oats are grown in many regions of the world. The words "porridge," "parritch," and variants are allied to the word "pottage," indicating the practice of cooking ingredients together in a pot and thickening it with cereals, though "pottage" itself came to mean soup or broth. They may also be linked to *porray*, which is derived from *porrum*, the Latin word for leek—an age-old pottage vegetable. The Scottish *purry* was a mixture of oatmeal and kail.

#### Cooking and Serving

Traditions surround the making and eating of porridge. Stirring should always be done clockwise (for luck) with

## DEVELOPMENTS

In 1877 the Quaker Oats Company of the United States developed rolled oats or oatflakes by steaming and rolling the coarsest grade of oatmeal—the so-called pinhead oatmeal, which is the whole grain halved. This innovation simplified the preparation of porridge and all oat-based dishes.

The muesli of today, regarded as a health food, is generally formulated with oats as its principal ingredient, with the addition of other cereal flakes, dried fruits, and nuts. It requires no cooking and has grown more sophisticated over time, but it is still recognizably a derivative of the Scottish porridge.

Pewter porringer (*écuelle*) with lid. France, circa 1740. The rustic porringer, which throughout the Middle Ages provided hearty sustenance for kings and peasants alike, reached its zenith of elaborate detail in eighteenth-century France. ROUGHWOOD COLLECTION. PHOTO CHEW & COMPANY.

a *spirtle* or *theevil*, a wooden stick tapering to a rounded point, for stirring, and a carved head. In Scots, porridge was always referred to in the plural and was customarily eaten while standing, but the reasons for this latter custom are obscure. Some aver it was due to the proverb: “A staunin’ sack fills the fu’est” (A standing sack fills the fullest), while others consider folk ate standing up lest an enemy catch them unawares.

Once cooked, the porridge was ladled into porringers (bowls) with a separate bowl of milk, buttermilk,

or thin cream close by. Each spoonful of porridge was dipped into the cold liquid and then eaten. Some sprinkled sugar over the porridge, and others preferred honey, treacle or syrup, or a knob of butter—the men might replace the milk with ale or small beer. Porridge was sometimes poured into a drawer in the kitchen dresser to be sliced when cold, either for eating out in the fields or for reheating in the evening.

The basic mixture allowed for numerous permutations, all with their own nomenclature according to locality. Brose was made by pouring boiling water over oatmeal, butter, and salt: with meat stock it became fat brose, while the addition of a green vegetable gave kail brose. Hasty Pudding was a form of porridge enriched and sweetened. Gruel was made by boiling the liquid that oats had soaked in, flavoring it with assorted ingredients and allowing it to cool to a jellylike substance. To make *sowans*, oat husks were soaked until sour, at which point the mixture was sieved and the husks thrown out. The liquid was a pleasant drink and the starchy sediment underneath was boiled and eaten either hot or cold, with milk, cream, or beer again served separately.

Oatmeal augmented every type of dish and some drinks, too, while assorted oatcakes and bannocks baked on a girdle (a flat iron plate hanging over the fire) took the place of yeasted bread.

Porridge is highly nutritious because oatmeal contains protein, carbohydrate, fats, and soluble fiber, all the B vitamins, vitamin E, calcium, and iron. The lack of vitamins A, C, and D is redressed when it is combined with milk or vegetables. Research has revealed that porridge might aid in the prevention of coronary heart disease as well as in the treatment of hypertension and certain diabetic conditions.

## MAKING PORRIDGE BY THE TRADITIONAL SCOTTISH METHOD

For each person allow about a handful of oatmeal to half an (imperial) pint of water and a small teaspoonful of salt. Bring the water to the boil and add the oatmeal in a slow but steady stream, stirring briskly. Once it has returned to the boil simmer gently until cooked, about 20 to 25 minutes. Add the salt near the end of the cooking time.

Quantities are necessarily inexact as meals vary, as do the tastes of those eating the end product. Rolled oats require less cooking, so follow the manufacturer’s instructions; the microwave, too, shortens the cooking time.

## A Scottish Staple

The consumption of porridge, together with other oat-based products, is considered an essential benchmark of Scottish nationality. In the geographical and climatic conditions of Scotland, both oats and barley provided a more reliable harvest than did wheat, but oats did not predominate until the eighteenth century. Thereafter, they played an increasing role in the diet, particularly in rural areas where oatmeal often formed the basis of every meal: "Oatmeal, with milk, which they cook in different ways, is their constant food, three times a day, throughout the year, Sunday and holidays included," observed J. Donaldson in 1794 regarding the farm laborers in the Carse of Gowie, a fertile area along the River Tay's north bank. Places in England and Wales with similar conditions saw a parallel dependence on oatmeal. Emigrants from the United Kingdom, but most especially the Scots, took their traditional habits with them, including their food preferences, and oatmeal was subsequently exported to many far-flung corners of the globe.

**PORRIDGE, POTTAGE, GRUEL.** In Great Britain, porridge is synonymous with hot oatmeal gruel, a common breakfast food that also has become an icon of Scottish cookery or at least an icon of presumed Scottish origin. Food packaging and mass-market advertising have helped create this mythology, but in fact porridge is a universal dish that cuts across many cultures and geographic boundaries. Furthermore, oats are not a defining feature. They do not even play a role in the origin of the word "porridge."

The old children's rhyme moves closer to the real meaning of porridge: "Peas porridge hot, peas porridge cold, peas porridge in the pot nine days old." The key ingredient here is not oatmeal but peas, and not fresh peas but rather dried peas cracked into grits. The dried pea probably was not the only ingredient in peas porridge, because porridge, the original porridge, was a vegetable preparation, not a dish based on cereal grains (as in the case of gruel). The etymology of porridge has not been neatly worked out because the chain of evolution has a number of missing links, but this much is clear: porridge shares a common ancestry with words like "pottage," "porringer," "puree," and "potage," the latter the French word for soup. This word family also includes *potager*, the hearth where vegetable soups were boiled, and by extension the kitchen garden, in which those ingredients were grown.

The presumed underlying link for all of these concepts is the Latin word *porrum* or *porrus*, a leek. It appears in the Middle English word *porree*, a term used for leek porridge. It would seem, from etymological evidence, that originally porridge was a preparation made from leeks (or green onions resembling leeks) and secondarily from other ingredients in the kitchen garden. In home cookery this type of porridge may have been relatively coarse, with the ingredients chopped or pounded, then stewed until tender. In court cookery, where more attention was paid to delicate textures, leek porridge was most probably served as a smooth purée thickened with bread—many medieval recipe collections contain directions for making just this sort of dish. It finds its counterpart in the modern-day Spanish preparations known as *porra*, which are made by pounding the ingredients in a mortar until they form a thick pulp. They are eaten like gazpacho, scooped up with a piece of bread rather than with a spoon.

A parallel theme in all of these dishes is the fact that they are thickened in some fashion. The most elegant medieval preparations were thickened with white bread, yet presumably lower down on the economic ladder poorer cooks used whatever coarse thickeners were on hand. Dark bread was one alternative. Animal blood, especially the blood of fowl or hogs, was certainly employed during the butchering season. Combining pounded vegetables with meal or grits was also one common solution. In southern Europe barley, emmer wheat (*farro* in Italian), or millet appear to have been the thickeners of choice among the peasants. In northern Europe oats, barley, and rye were commonly employed, depending on what was most abundant in a particular region. The great variation in the use of thickeners may have given rise to the idea of national "styles" of porridge, when in fact national identities as understood in the twenty-first century are of recent origin. While the British may be inclined to call prepackaged oatmeal gruel a porridge, historical evidence suggests that if indeed it was once a porridge, it has been stripped of all key vegetable ingredients, most importantly the leeks.

**POTATO.** The potato is a tuber—a short, thick, underground stem with stored starches and sugars—of the potato plant. It was given its botanical name, *Solanum tuberosum*, in 1596 by the Swiss botanist Gaspard Bauhin, and belongs to the Solanaceae family, the nightshades, which includes eggplant, peppers, and the tomato. (The sweet potato is not a potato; it belongs to the morning glory family.) Growing wild as early as 13,000 years ago on the Chilean coast of South America, potatoes were first cultivated by farmers in the Andes Mountains nearly seven thousand years ago.

Nutritionally, the potato supplies complex carbohydrates—essential for energy—and a very low amount (about 10 percent) of protein. One serving (a 5.3-ounce medium potato) provides: 45 percent of Recommended Daily Intake (RDI) for vitamin C (most of it in the millimeters-thick layer immediately under the skin), 21 percent of potassium, 3 grams of fiber, essentially no fat, and only 100 calories. It is rich in the minerals iron and magnesium and supplies all the vital nutrients except calcium and vitamins A and D.

Potatoes are the vegetable eaten most frequently in the United States, and the one ordered most when Americans eat out. In 2001, the average American ate 41 pounds of potatoes. In 1996, the annual per capita consumption increased with age among those over eighteen: between eighteen and thirty-four, 74.3 pounds; thirty-five to forty-four, 80.6; forty-five to fifty-four, 87.4; fifty-five to sixty-four, 88.9; and, for those sixty-five and older, 109 pounds. Interestingly, consumption again peaked among those between thirteen and seventeen (83.2 pounds) and six to twelve (85.5 pounds), who presumably consume most of their potatoes as french fries, chips, and novelty forms.

The United States ranks fourth in world potato production, with an estimated 1.26 million acres planted in 2001. Russia is the largest producer. With a world harvest of 291 million tons grown in more than 100 countries, potatoes are second only to rice as a world food crop.

### South American Origins

The potato was domesticated high in the Andes Mountains in South America by 3000 B.C.E., but it was not until the Incan civilization (ca. 100–1530 C.E.) that the tuber's true agricultural potential was realized. The climatic challenges of growing crops in the heights of the Andes are formidable. Radical swings in temperature, from highs of 62°F (17°C) to lows below freezing (most nights of the year), occur even within a twenty-four-hour period, and constantly disrupt the potato plant's physio-

logical processes. Yet, potatoes are ideally suited to these conditions; the plant grows in even the poorest soils, and the hardiest species can survive at an altitude of 15,000 feet.

The Inca devised agricultural innovations that maximized the potato crop. The introduction of terracing enabled steep slopes to be planted. A system of canals efficiently distributed water from higher in the mountains to each terrace level. In the absence of plows and oxen, a wooden foot plow called a *taccla* was invented that is still used in the Andes today. A representation of this tool is found in a Spanish woodcut from the late sixteenth or early seventeenth century (but the tool is presumed to predate that). The Inca wisely prized agricultural diversity, growing 3,000 varieties of potatoes in various sizes, textures, and colors. Their goal was to develop a different kind of potato for every type of soil, sun, and moisture condition. Thus, the rulers could secure a high yield of potatoes—enough to feed thousands of members of the expanding empire—from disproportionately small plots of land.

The Inca also serendipitously discovered how to freeze-dry potatoes. At night, the cold of the Andes froze the tubers. (Raw potatoes are 80 percent water.) During the day, however, they thawed in the warmth of the sun. As they defrosted, laborers stamped on them to press out all the moisture. After several days of alternating freezing and defrosting, the potatoes were dehydrated and transformed into a lightweight, transportable substance known as *chuno*. Stored in sealed, permanently frozen underground storehouses, the freeze-dried potatoes kept for five or six years. When needed for sustenance during the lean months, the *chuno* could be reconstituted by soaking in water, then being cooked or ground into meal, with no loss of nutritional value. *Chuno* was so precious to the Inca that it was used as currency and collected as tribute. It was also believed that potatoes have healing properties. Raw slices were placed on broken bones, aching heads, and rubbed on bodies to cure skin diseases, and slices were carried to prevent rheumatism.

### From South America to Europe

When the Spanish arrived in South America around 1537, they were not impressed by the potato. The strange tubers, misshapen and bitter, were about the size of peanuts, and bore little resemblance to potatoes we know today. The Spanish mistook them for a kind of truffle, calling them *tartuffo*. The Inca routinely consumed the choice, large tubers, and planted only the rejects, thereby propagating progressively inferior tubers.

Gradually, the Spanish realized that potatoes were perfect food for sailors on ships returning from Peru. The tubers traveled well, were cheap, nutritious, required little preparation, and prevented scurvy. Returning to Spain by way of sub-Saharan Africa, the Spanish introduced potatoes there in 1538. Leftovers from shipboard food found their way to Spain in the 1550s but, in most areas,

## HEIRLOOM POTATOES: THE PURSUIT OF OLD-TIME FLAVOR

While the discussion over genetic diversity in crop potatoes has polarized the agricultural community today in much the same manner as the finger-pointing during the 1850s over the causes of the 1840s potato blight, market forces are quietly building new niches for time-tested heirloom varieties. Limited choices in the supermarket and hybrid potatoes without much character or flavor have sent frustrated chefs and small growers in search of the old standbys that once made home cooking so memorable. Interest began with the “fifty-somethings,” the not-quite-antique varieties like the Pimpernel (1953) developed in Holland and the French yellow-fleshed fingerling called Roseval (1950). Both are good producers with very distinctive cooking qualities.

Those criteria have become important again, especially since heirloom potatoes are different from heirlooms passed down via seeds. Heirloom plants are generally defined as open-pollinated varieties that have been handed down over several generations, with particular emphasis on varieties dating from before the 1940s. Because potatoes are increased by planting pieces of tubers, they are genetic clones of their parents. That is why heirloom potatoes actually taste like the past. Potato classics like pink-skinned Early Rose (1867), developed by Albert Bresee of Vermont, and creamy 1840s Peach Blow from New Jersey sell out as quickly as growers can supply them. What better potato was ever invented for mashed potatoes, gnocchi, or dumplings than

the aptly named Snowflake (1874)? Steam it, and it turns to fluffy snow.

The growing affection for heirloom potatoes is not just a grass-roots trend in the United States and Canada. Arche Noah, a private seed organization in Austria, has been building up an heirloom potato collection for many years, and the recently organized Association Kokopelli in France is establishing chapters in most of the leading countries in the European Union. Kokopelli is comparable to a horticultural Slow Food movement, and doubtless one food network will soon be influencing the other. Purple-skinned treasures like Violette du Lac Bret, a rich-flavored blue potato from Canton Vaud, Switzerland, and its cousin Vitelotte noir (1815) of France are finding their way onto the leading restaurant tables in those countries, just as La Ratte d'Ardèche (1872) has now become the salad potato most favored by Paris chefs.

In the British Isles, waxy yellow Duke of York, developed in Scotland in 1891, still reigns as the classic salad potato of choice. Lilac-skinned Arran Victory, developed in 1918 by Donald Mackelvie of Lamlash, Isle of Arran, Scotland; and Archibald Findlay's Catriona (1920), splashed with patches of blue on the skin, are considered by connoisseurs to be among the finest-tasting potatoes ever developed. Their flavors are complex, with hints of walnuts or hazelnuts, or, as some enthusiasts claim, Scotland's answer to truffles.

*William Woys Weaver*

The potato market in Elmer, New Jersey, 1907. Note the complete absence of motor vehicles. ROUGHWOOD COLLECTION.

they did not grow well and were not popular. Still, as early as 1570, potatoes could be purchased in markets in Seville, and, by 1573, they were being fed to hospital patients in other parts of Spain.

Through the first half of the seventeenth century, potatoes were eaten primarily by the poor and soldiers in Spain. In 1653, however, the historian Bernabé Cobo made a laudatory reference to the culinary properties of *chuno*, describing how Spanish women were able to grind the substance into more white flour than could be obtained from wheat, and from which they made sponge cakes and pastries with almonds and sugar.

Not until 1760 did Spanish plant breeders start to improve the potato. Eventually, it was found that potatoes grew well in the mountainous Pyrenees and along the Atlantic coast, where they were popular among Basque fishermen during their voyages to the Grand Banks of Newfoundland.

### The Potato Diaspora

From Spain, potatoes spread to all parts of Europe. Spanish ships carried the vegetable to Italy around 1560, making that country the first after Spain to eat potatoes on an appreciable scale. Potatoes also traveled along the “Spanish road” that connected Spain’s imperial provinces in northern Italy with the Low Countries.

By 1600, the potato had entered Austria, Belgium, Holland, France, Switzerland, England, Germany, and, most likely, Portugal and Ireland. Some historians claim that it was Basque fishermen who first brought potatoes to Ireland, when they came ashore to dry their catches on their return voyages from Newfoundland. Others maintain it was Sir Walter Raleigh who planted the first potatoes on his estate in Ireland. The potato was introduced in India, possibly as early as 1615, and had reached the most remote parts of China by 1643. Beginning about 1730, the Scottish Highlands adopted potatoes as completely as Ireland had.

### Fear of Potatoes

It is not unusual for new foods to be met with skepticism and fear, especially those arriving from a strange, faraway continent where they are consumed by “uncivilized” non-Christian peoples. The potato, however, had a tougher battle for acceptance than many other foodstuffs introduced from the Americas. Aside from its odd, unaesthetic appearance and initially bitter taste, the tuber was feared for a variety of reasons. Since it was not mentioned in the Bible, it was often associated with the devil. As a consequence, in the north of Ireland and in Scotland, Protestants flatly refused to plant them. In Catholic Ireland, to be on the safe side, peasants sprinkled their seed potatoes with holy water and planted them on Good Friday.

Another source of prejudice against the potato was its membership in the nightshade family, which includes a number of poisonous members: deadly nightshade (bel-

ladonna, which is poisonous), mandrake (known as a soporific and fertility drug), tobacco, and henbane (poison). Some of these substances have traditionally been associated in various cultures with magic and witchcraft. In many folk beliefs there is a grain of truth. Solanine, contained in the tubers and common to all plants in the nightshade family, is indeed a poison. Unlike modern potatoes, which contain only a nonharmful trace amount, tubers of the sixteenth and seventeenth centuries had much higher levels, not enough to cause death, but sometimes a rash appeared. That led to its association with the deadliest disease of the time, leprosy. So great was the fear that, when Frederick the Great of Prussia ordered his people to plant potatoes in 1744, they pulled them up. Frederick was forced to post soldiers to guard the crops. Ten years later, in 1754, the king of Sweden also ordered his subjects to grow potatoes. Yet, when famine struck Kolberg in 1774, wagonloads of potatoes sent by Frederick were rejected.

All over Europe, it was believed that the potato plant would bring disease. In the seventeenth century, the parliaments of Franche Compté and adjacent Burgundy actually prohibited its cultivation. In the early nineteenth century, Ludwig Feuerbach and other German radicals believed that “potato blood” was weakening the people and delaying the anticipated revolution. In Sicily, potatoes were used like voodoo dolls: the name of an enemy was attached to a tuber and buried in the belief that this would ensure his or her death. Even as late as 1928 in America, Celestine Eustis, the author of *Cooking in Old Creole Days*, advised readers to throw out the water in which potatoes had been boiled because it was poisonous.

At the same time potatoes were feared and reviled, and being grown only in the gardens of botanists, there was also a developing literature in sixteenth-century European herbal books asserting that potatoes had some therapeutic effects. Among the diverse claims were enhanced sexual desire, fertility, and longevity, and cures for diarrhea, tuberculosis, and impotence.

### The Potato in Time of War

Europeans quickly discovered that the potato afforded them a military advantage; it was ideally suited to combat starvation caused by war. During the Dutch Wars (1567–1609), for example, Spanish soldiers crossed the Alps on foot from Italy, marching north through Franche Compté, Alsace, and the Rhinelands. Villagers along the route quickly discovered that tubers carried by the soldiers could be planted, hidden underground, and dug as needed, unlike grain. Nearly every military venture after about 1560, including World War II, resulted in more acreage being planted in potatoes.

When French, Austrian, and Russian armies invaded Prussia during the Seven Years War (1756–1763), peasants escaped starvation by eating potatoes. As a result, the Austrian, Russian, and French governments all persuaded their own peasants to grow potatoes. In 1778, the

War of the Bavarian Succession was called “the potato war” because most of the action consisted of destroying the enemy’s food supplies.

In Russia, crop failure in 1838–1839 convinced people in central and northern parts of the country to raise potatoes. In the course of the nineteenth century, potatoes displaced bread as the principal food for poorer classes from Belgium to Russia. They were cheaper than bread, required less preparation, and were just as nutritious.

### Potatoes in England

Potatoes appeared in the British Isles in the 1590s. The historical record is unclear about which of two famous explorers introduced them, Sir Francis Drake or Sir Walter Raleigh. Regardless, the first English potatoes did not, contrary to popular myth, originate in Virginia. This mistaken notion gained credence because the first tubers destined for England passed through Virginia after having been taken aboard in South America.

The tubers were not immediately embraced in Great Britain, remaining a garden crop grown by botanists until 1780. The English, traditionally not fond of vegetables, based most of their meals on meat, and the potato carried a social stigma as the food of savages and peasants. The earliest potato crops in England were produced to feed sailors. By 1700, a stew called *lobscouse*, consisting of potatoes, meat, onions, and strong seasonings, was recorded in Lancashire. When hardtack was added as an accompaniment, lobscause became the standard dish of choice for shipboard crews. Yet, the tuber was so despised during the reign of George III (reigned 1760–1820) that it took years of botanical experiments before the English conceded that potatoes might be acceptable as cattle feed.

In the 1700s, northwest England began to produce an abundance of potatoes, as many as 13.5 tons per acre. Cultivation occurred, too, in Cornwall and outside London, where industry was beginning. In many ways, the potato fueled the Industrial Revolution; it was good, cheap food for another lowly multitude—workers. This trend was also generated by the simultaneous decline in bread production. In 1832, the Bread Acts were rewritten so potato flour could be used without losing the right to call the product “bread.” By 1836, two million people who used to subsist on wheat flour—one-seventh of the population—were living chiefly on potatoes. By 1850, Londoners were consuming 3,000 tons of potatoes a week. Baked potatoes played a special role in London working-class life—they were sold by street vendors both to eat and to use as hand warmers.

The perennial British working-class favorite, fish and chips, reached the streets as two separate dishes, with fish coming at least thirty years before chips. Neither was fried in deep fat until the 1860s. By 1888, there were between 10,000 and 12,000 fish-and-chips shops in the United Kingdom serving the duo wrapped in newspaper and sprinkled liberally with vinegar.

Meanwhile, the elite consumed potatoes in very different forms—disguised as other foods. Unadulterated, naked potatoes were not considered appropriate food for the upper classes, and Queen Victoria’s chef carved the tubers into shapes like olives and pears, or buried them entirely in purées and soups. By 1914, however, people in England said they would rather pass up greens, butter, and nearly all their precious meat before they would give up potatoes—quite a change of heart. It was the English who coined the word “spud” for potato, a slang expression that originally referred to a potato-digging spade.

### The Great Irish Potato Famine

Ireland was the first country in Europe to accept the potato as a field crop, in the seventeenth century, and to embrace it as a staple in the eighteenth. To the poverty-stricken peasantry, this tuber was a safeguard against unemployment, overpopulation, crop failure, and starvation. Landless laborers rented tiny plots that they sowed with potatoes. One acre could feed a family of six, averaging ten pounds of potatoes per person a day. Potatoes did not replace meat immediately, but other staples like oats, beans, barley, herring, and bread gradually disappeared from the table. Over time, the diet shifted to one of boiled potatoes supplemented by milk, which supplied calcium and vitamins A and D, making the meal nutritionally complete.

As early as 1740, the potato saved Ireland from famine. Between 1780 and 1841, when the potato achieved its dominance, the population doubled in Ireland. According to historic sources, it cannot be said with certainty that the potato was responsible, but surely it played a role. By 1845, about 40 percent of the Irish population was dependent on the tubers raised on 65,000 farms of not more than one acre each. Potatoes were also used to feed pigs.

In 1845, blight struck potato fields throughout Europe, but those most devastatingly affected by the fungus *Phytophthora infestans* were in Ireland. The assumption is that the blight was carried back by ship from North America on a diseased tuber. Livid purple patches appeared, covering whole potato plants—roots, tubers, and foliage—after which they turned brown and rotted. Whole fields went under in a matter of hours, destroying 40 percent of the crop. Yet, few deaths occurred because many people slaughtered their pigs, which normally ate a third of the crop. In 1846, the blight redoubled, killing 90 percent of the potatoes and preventing a new crop from being sown. The fungus was not as virulent in 1847, but reappeared in full force in 1848–1849. About five to six months later, famine set in, and diseases including typhus, dysentery, relapsing fever, respiratory infections, and cholera were not far behind. Ultimately, two million people died, one-quarter of the entire population. One million immigrated to the United States.

## How the Potato Twice Changed World History

The historian William H. McNeill (1999) believes that potatoes twice made a critical difference in world history: first, in South America, where the vegetable provided the principal energy source for the Inca and their Spanish successors. There would have been no great Incan civilization, McNeill contends, without *chuno*. Not only was it collected as taxes from the peasant-farmers, it was also disbursed from storehouses to pay labor gangs for building roads, waging war, and erecting great monuments. Once the Spaniards arrived and conquered the Inca, *chuno* is what fed thousands of conscript miners, forced by the conquistadors to work the silver mines in Bolivia. This tremendous influx of silver contributed to worldwide monetary inflation, and enabled Spain to build a powerful naval fleet.

The second way in which the potato changed world history was in northern Europe. The extraordinary strength of the industrial, political, and military changes between 1750 and 1950 could not have taken place without an enormously expanded food supply from potatoes, which served to feed a rapidly growing population, McNeill argues. Germany could not have become the leading industrial and military power of Europe after 1848, and Russia could not have assumed so threatening a stance on Germany's eastern border after 1891. Both events helped set the stage for two world wars.

## The Potato Becomes Haute Cuisine

The French were no more enamored of the potato at first than any other Europeans. Legrand d'Aussy, in his 1782 *Histoire de la vie privée des Français* (History of the private life of the French) wrote that the pasty, indigestible tuber should be eliminated from aristocratic households and left to the poor. Also in 1783, a Parisian gourmet expressed outrage that the potato had achieved a certain cachet in the capital. The nineteenth-century French gastronome and author of the esteemed *La physiologie du goût* (The physiology of taste, first published in 1825), Brillat-Savarin agreed that the tasteless potato was good only as a defense against famine.

As in other European countries, the peasantry took to potatoes much more quickly because it could be used in their diet like turnips. Around 1620 (during the reign of Louis XII), the Abbey of Remiremont accepted payments in potatoes. As early as 1673, the tubers were being cultivated on a large scale in Lorraine. By the first half of the eighteenth century, the potato was well established in France, even if it was only among the peasants. By the middle of the century, potatoes began to be grown in the Pyrenees and Dauphiné, both very mountainous areas. By 1780, potatoes were the chief food of the Pyrenean highlands. By 1840, the potato was well established in French cuisine, making its way in through the soup pot, where it added bulk and absorbed flavors.

The person most credited with winning acceptance for the potato in France was eighteenth-century army

pharmacist Antoine Parmentier. As a prisoner in Germany during the Seven Years War (1756–1763), he was forced to eat potatoes almost exclusively and became convinced of their virtues. He set about analyzing their chemistry. Then he won a competition sponsored by the Academy of Besançon to identify foods that could stem mass hunger after the famine of 1770. To counter the fear of anything in the nightshade family (more intense in France than in England), in 1771 the Faculté de Paris published a paper stating emphatically that the potato was innocuous. After yet another famine, Parmentier himself wrote in 1789 that, although the tuber was a nightshade, it was not soporific. To further convince the populace of the potato's appeal, he had the tubers planted on the worst possible land on the outskirts of Paris. During the day, the field was guarded by soldiers who left at night. The peasants, intrigued by such an important crop, went into the field and stole potatoes to plant in their own gardens, which is exactly what Parmentier wanted to happen.

Realizing that acceptance of the potato needed to begin at the top, Parmentier is said to have convinced Louis XVI to encourage planting and eating the tuber by throwing all-potato banquets. Even Marie Antoinette was said to wear potato flowers in her hair at court. Although these colorful stories may be apocryphal, between 1770 and 1840 potatoes became widely cultivated in northern parts of the country. When famine struck in 1788 because the grain crop failed, potatoes were available.

In 1793, during the “Reign of Terror,” the French people celebrated potatoes as their republican salvation. Even the royal Tuileries gardens were symbolically converted into a potato field. Realizing the political strength potatoes could provide, the Republic published ten thousand copies of a pamphlet on cultivation. A year later, a cookbook, *La cuisinière républicaine*, presented twenty recipes. The annual potato crop burgeoned from 59,640,000 bushels in 1815 to 332,280,000 by 1840. By 1843, France produced almost half a million bushels of potatoes, possibly the largest crop on the continent and in all of Europe.

Potatoes gradually acquired a place in haute cuisine. Collinet, the chef for King Louis Phillippe (reigned 1830–1848), accidentally created the famous *pommes soufflées* (puffed potatoes) when he plunged fried potatoes into extremely hot oil to reheat them when the king was late for dinner. Much to the chef's surprise, the potatoes puffed. *Pommes frites* (what we call french fries) appeared on city streets in the north of France around 1870. The Larousse *Gastronomique*, the encyclopedia of French cuisine, first published in 1938, contains dozens of classic French recipes for potatoes.

## The Potato in America

While potatoes migrated from South America to Europe, they failed to travel out of South America to North America or even to Central America and Mexico. In fact, Mexico did not have potatoes before the eighteenth century.

It took about two hundred years—after the tubers made their way to Europe—before they were introduced into North America. This may have happened as early as 1613 in Bermuda, and on the mainland in 1621. The first North American colonial potato growing dates from 1719, when Irish immigrants, escaping starvation from the famine, introduced the potato to New Hampshire.

Americans did not subject the potato to class distinctions, so its popularity grew rapidly. In 1806 the American Gardener's Calendar included only one variety of potato; by 1848, almost one hundred kinds were exhibited at the Massachusetts Horticultural Society fair. By 1860, American output of potatoes was calculated at 100 million bushels, 90 percent produced by the northern states, with New York the single largest producer, followed by Pennsylvania, Ohio, and Maine.

A major step forward in potato cultivation was made in 1872 when the botanist Luther Burbank discovered that the Early Rose potato produced a seed ball, and was able to breed plants with larger tubers whose yield sometimes doubled or tripled that of its parent. The resulting progeny became known as the Burbank potato, which a few decades later mutated into the Idaho (or Russet).

For nineteenth-century farming life, the potato was a real boon for the same reason it became popular elsewhere as a cheap, nutritious, convenient way to feed farmhands and families. The potato, however, was not kept down on the farm; in 1876, some American hotels offered five different potato dishes for breakfast. During the Alaskan Klondike gold rush (1897–1898), potatoes were at times almost worth their weight in gold, so valued for their vitamin C that desperate miners traded gold for them.

In October 1995, the potato became the first vegetable to be grown in space. NASA and the University of Wisconsin created the technology with the goal of feeding astronauts on long space voyages, and, eventually, feeding future space colonies.

### Cultivating Potatoes

Potatoes are most often grown in cooler climates in moist, acidic soil (pH slightly less than 6). They must be able to gather sufficient water from the soil to form the starchy tubers that range anywhere from three to twenty in number on any one plant, depending on variety, weather, and conditions. In the United States, most potatoes are produced in Idaho, followed by Washington, Oregon, Maine, North Dakota, California, Minnesota, and Wisconsin. Six varieties account for 80 percent of the crop yield.

Although potatoes are perennials, they are treated as annuals since the edible part of the plant that contains the buds is dug up each year. Farmers grow particular tubers as seed potatoes (not intended to be eaten) for propagating new crops. These potatoes are cut into what are called “sets,” small pieces, with at least one eye or leaf

bud on the surface, with some of the flesh of the potato still attached to supply the initial energy for the plant. The sets are planted with the eyes facing upward; new plants sprout from the eyes.

The potato plant produces leaves and flowers that can be white, purple, lilac, or violet, depending on variety. If fertilization of the flower is successful, a small green fruit ball is produced containing fifty to two hundred seeds, known as true seed. These can be planted for the next year's crop rather than using seed potatoes. The leaves supply abundant food for the plant's growth, and the generated surplus moves down into the underground tuber for storage. Potatoes can be left in the ground for four to six weeks. They are harvested when all of the leaves and tops of the plants have withered. A potato that is harvested young, usually in the spring or early summer, and sent directly to market instead of being stored, is known as a new potato.

Before potatoes can be sold or shipped, they must be sorted for size and quality. This process is called “grading” and special implements are used. These can be as simple as a wooden slat with a bag on the end for acceptable potatoes, or a more complicated conveyor-belt system that moves potatoes toward the bag at the end as inspection is performed.

Potatoes produce the steroidal alkaloid solanine, which seems to protect the tubers and foliage from some predators and insects. Still, potatoes are vulnerable to such pests as the Colorado potato beetle, red slugs, and blister beetles, and are still attacked by blight. Since 1990, fungicide-resistant strains of blight have struck fields in various parts of North America.

### Culinary Preparation of Potatoes

Potatoes figure prominently in many of the world's cuisines, particularly in the Americas, in Europe, and in countries colonized by Europeans: *pommes de terre soufflées* and *pommes Anna* in France; hot potato salad, noodles, dumplings, pancakes, and bread in Germany; as a base for soups and puddings and stuffing for pierogi in Russia and Poland; colcannon—a mixture of potatoes and kale, turnips, or cabbage—and cobbledy, potatoes mashed with milk, butter, salt, pepper, and onions in Ireland; as an ingredient in the Spanish omelette; in the latkes and knishes of Jewish food; for the sauce *skordalia* in Greece; in *raclette* and *roesti* in Switzerland; for gnocchi in Italy; stuffed potatoes and savory *causa*, mashed potato cake, in Peru; for *lefse*, thin potato pancakes in Norway; in fish and chips, mashed potatoes, shepherd's pie, and Cornish pasties in England; potato casserole in Finland (*Imellettyperunasoselaatikka*), a dish that undergoes a malting process wherein the starch of the potatoes breaks down to form a simple sugar; french fries, potato chips, and stuffed potatoes in the United States.

Potatoes can be used in every course of a meal, even dessert. They can be fried, boiled, steamed, braised,

roasted, sliced, diced, chopped, and mashed. A large part of their versatility is their neutral taste, which provides a palatable backdrop for almost all other foods. For dessert, potatoes can be used with or without chocolate in cakes, pies, doughnuts, cookies, and candies. Since potatoes contain no gluten, adding some mashed potato to dough makes it particularly tender.

For cooking, potatoes are classified according to starch content—high, medium, or low—which affects the way they cook and the resulting texture. High-starch potatoes (Russets and Idahos), also known as mealy or floury, are the first choice for baking and frying. The use of the microwave to bake potatoes has considerably shortened what used to be a lengthy process. The large starch granules swell up and separate, making for a light and fluffy texture. Medium-starch potatoes (white all-purpose and yellow-fleshed, including Yukon Golds) have a creamy texture and become soft but do not disintegrate when cooked. Low-starch potatoes (round red and white boiling potatoes), also known as waxy potatoes, are the first choice for boiling, steaming, and roasting. They contain more of the starch known as amylopectin, with granules that stay close and dense even after cooking.

Once purchased, potatoes need to be stored in a dark, but dry, place to ensure they do not turn green or sprout. Generally, store-bought potatoes have been sprayed with a chemical that inhibits sprouting. Even a little warmth and light, however, may provoke the eyes to use the stored energy in the tuber for growing.

The substance that sometimes appears as a greenish cast under the skin and in the eyes of the potato is the alkaloid solanine, the natural pesticide that protects the plant as it grows. All potatoes contain trace amounts (1–5 mg). Its appearance on store-bought potatoes means they have been “light-struck,” exposed either to natural or artificial light. According to Federal Food and Drug Administration guidelines, levels higher than 20 mg per 100 g of potato make the vegetable unfit to eat. Consequences of solanine toxicity range from minor upset stomach to serious illness. To avoid this, proper storage and cutting away all traces of green on the potato are necessary.

### **Relation to Human Biology**

Potatoes contain anthoxanthins, pigments that produce the white color and act as antioxidants, believed to have some cancer-preventing activity. Specifically, unfried potatoes are among those vegetables containing the highest levels of the antioxidant glutathione. When compared to bell peppers, carrots, and onions, potatoes have the greatest overall antioxidant activity. Only broccoli is higher.

French fries and potato chips, however, may pose a cancer risk. Separate studies by the national food agencies of Sweden, Britain, and Norway have reported high levels of acrylamide, a carcinogen in rats and probably one in humans, in potato products fried at high temper-

atures. Until there is more evidence, the World Health Organization and the United Nations Food and Agriculture Organization have not been able to determine whether consumers should cut back on their intake of fried potato foods, particularly chips.

Eating unfried potatoes contributes to the minimum goal of five servings of fruits and vegetables a day, recommended by the U.S. Department of Agriculture’s (USDA) Food Guide Pyramid and designed to provide optimum good health.

### **Symbolism of the Potato**

In the United States, the potato has found its way into pop culture. A “couch potato” is a sedentary person; “hot potato” indicates a volatile issue or topic; “small potatoes” refers to something that is not a big deal; a “meat and potatoes” person is someone who eats only the basics. Calling someone a “potato head” is not a compliment because it means someone who is dense. A familiar children’s rhyme begins, “One potato, two potato, three potato, four.” The children’s toy Mr. Potato Head®, introduced by Hasbro in 1952, and Mrs. Potato Head®, in 1953, came packaged with plastic eyes, ears, nose, mouth, feet, and hats to insert into a real potato supplied by the buyer. In 1960, the kit also came with a potato-shaped plastic body. The image has been licensed worldwide for a variety of popular uses including T-shirts, clocks, and Halloween masks.

Since its earliest appearance in Europe, the potato has been associated with the poor and the working class. When the Spanish first stumbled on the potato in Peru, they looked down on it as slave food. The exotic sweet potato was brought from Haiti to Europe as soon as it was discovered by Columbus, but it took the conquistadors more than thirty years to bring potatoes to Spain, and then they came as food for sailors. For a long time, the potato continued to be regarded as food fit only for the poor and as animal fodder, useful only in the event of starvation.

In America, where the potato did not have a class barrier to break down, its association with fat and grease—deep frying—has reinstated some of its lowly image. A headline a few years ago in the *New York Times* read, “The Rich Get Richer and the Poor Get French Fries.” The irony is that, by cooking it in fat, the 99.9 percent fat-free fresh potato is transformed into a high-fat snack.

### **Commercialization of Potatoes**

An early reference to commercial potato growing dates from 1762, when the tubers became a field crop in Salem, Massachusetts. In the following year, Connecticut valley potatoes were listed as an export, but the buyers were West Indian planters, looking for cheap food for slaves. By 1848, about half a dozen varieties of potatoes were being grown commercially, the same number grown in the twenty-first century.

Processing of potatoes began not long after they began to be grown commercially. In the 1870s and 1880s in both France and America, manufacturers began making equipment for deep frying, which made commercial production of fried potatoes and french fries a reality. Mass production depended on the availability of cheap oils that appeared right after the Civil War. In 2002 in the United States, nearly half of the potato harvest ends up being fried.

Unfortunately, processing takes much of the taste out of potatoes, and undermines their quality as growers shift to varieties demanded by processors rather than those that are best fresh. Potato products are made from potatoes that have been reduced to powder in one of two ways. The first is simple cooking, drying, and grinding, which preserves the solids in more or less their original proportions. This is how potato flour is made. Derivatives of potato flour include instant mashed potatoes, frozen potato products, and potato chips.

The second method involves extracting starch from potatoes by a washing process. This is how potato starch is made, which is commercially packaged to be used as a thickener and to make cakes, biscuits, puddings, pies, and sauces for Jewish Passover to fulfill the religious requirement that no flour be used in their preparation.

The first large-scale production of dehydrated potatoes began in 1942, when the potato processor John Richard “Jack” Simplot, already the nation’s largest shipper of fresh potatoes, won a government contract to supply dried potatoes to the armed forces during World War II. By 1945, he had supplied about 33 million pounds of dehydrated potatoes to the military. French’s Instant Potato was introduced by the R. T. French Company in 1946. Frozen potatoes came later, at first simply precut for french fries. By 1962, frozen, dehydrated, and canned potatoes accounted for 25 percent of U.S. potato consumption. By 1966, per capita consumption had risen to 44.2 pounds a year, up from 6.3 in 1950.

### The Potato Chip

In 1853, that quintessentially American product, the potato chip, was invented serendipitously. Annoyed when Commodore Cornelius Vanderbilt (the railroad magnate) sent back his fried potatoes because they were too thick, George Crum, the chef at the Half Moon Hotel in Saratoga Springs, New York, thought he would teach him a lesson. Crum sliced some potatoes paper thin, deep-fried, and salted them. Vanderbilt loved them.

Potato chips began to be commercially manufactured as early as 1915, when Van de Kamp’s Saratoga Chips, a storefront operation, opened in Los Angeles. In 1921, Wise Potato Chips were introduced in Berwick, Pennsylvania, by Earl Wise, a local grocer. Finding himself overstocked with old potatoes, Wise peeled and sliced them, and then followed his mother’s recipe for making chips and put them in brown paper bags. In the early

1930s, he switched to the more practical cellophane bags. By 1942, Wise had opened a 40,000-square-foot plant.

In 1969, General Mills introduced Chipos, and Procter & Gamble brought out Pringles, both made from cooked, mashed, dehydrated potatoes that were then reconstituted into dough and cut to uniform size (rather than made from sliced potatoes fried in oil). These new “chips” were packaged in break-proof, oxygen-free containers to prolong their shelf life. The Potato Chip Institute sued to prevent the products from being sold as chips, but lost. The Food and Drug Administration ruled that chip products not made from fresh potatoes must be labeled “potato chips made from dried potatoes.” By the time the ruling was to have taken effect in 1977, fabricated chips had already lost their appeal.

In 2001 in the United States, nearly \$2.7 billion worth of bags were sold, according to Information Resources, a market research firm. A survey by the Department of Agriculture found that the average American snacker eats 33 pounds of chips per year.

### Issues in the Twenty-first Century

To combat the threat of pest damage and fungicide-resistant blight, scientists have experimented with breeding blight-resistant germ plasm and biotechnology that involves placing a gene into an already existing variety to improve its resistance to disease, insects, or stress. For example, resistance to the Colorado potato beetle has been placed into the Russet Burbank potato by inserting genetic material from the bacterium *Bacillus thuringiensis* into the plant. This causes a protein to be manufactured that disrupts the digestive system of the beetle when it feeds on the leaves. The Shepody variety of potato has been improved to make it more resistant to viruses, one of the major causes of declassification of seed in the potato industry. The gene prevents replication of a virus after it has been introduced by aphids. Monsanto’s NewLeaf potato is the first genetically engineered potato, designed to protect it from the Colorado potato beetle. It was approved in the United States in 1995, and subsequently in Canada, Mexico, and Japan. The NewLeaf Plus, the next generation from Monsanto, resists both the beetle and the potato leaf roll virus.

Biotechnology is not without controversy. Some critics point out that it gives corporations like Monsanto a profitable monopoly on the seed since it must be replanted each year. Others are concerned that the long-term effects are not known. A major concern is that there is no requirement to label genetically engineered products. There are even larger questions about whether biotechnology offers a reasonable way to feed the world’s hungry; most experts maintain that the amount of food is sufficient and it is distribution that is the crucial issue.

### Genetic Diversity

Many observers believe that the solutions to the agricultural issues lie in plant breeding and preserving the

genetic diversity of potatoes. By planting a larger number of varieties, farmers guard against damage of blight or insects that might destroy one variety but not another. There is some reason to believe that, if Ireland had planted its fields with a diverse crop, the toll from the famine would not have happened.

Today, only half a dozen varieties constitute the vast majority of the nation's crop. In the final decade of the twentieth century, there was a resurgence of interest in potato varieties and their preservation and development. Of particular interest are heirloom potatoes, those developed over centuries for which the seeds have been handed down from one generation to the next.

To protect the genetic diversity of the potato, and to make it available for systematic manipulation, the International Potato Center in Lima, Peru, under the auspices of the Consultative Group on International Agricultural Research, has collected about 5,000 samples of native cultivars from nine countries in Latin America, representing about 3,500 genotypes. Every aspect of the potato and its place in the environment and human society is studied. Recent projects have included an effort to develop tropical varieties for Africa, Hong Kong, and the Philippines.

**POTLATCH.** "Potlatch" is anglicized from the Nootka (Nuu-chah-nulth) word *patshatl*, which means "giving." The Nootka term came to be used in Chinook jargon, a Northwest Coast of North America lingua franca, in the 1860s with the beginning of Euro-Canadian settlement. Potlatch denotes a ceremonial feast and gift giving held in winter, usually marking a rite of passage, such as a funeral, wedding, or elevation to a noble title. Late nineteenth-century Kwakiutl (Kwakwaka'wakw) potlatches described by Franz Boas displayed oratorical boasting and overwhelming quantities of gifts and food, asserting the aristocratic host's wealth and high rank. Neighboring noble houses vied for even more generous potlatches, escalating the competition for status. For example, in 1803, a Nuu-chah-nulth chief gave away 200 muskets, 200 yards of cloth, 100 mirrors, and gunpowder; in 1921, a Kwakiutl chief gave away thousands of dollars worth of purchased goods, including gas-powered boats and boat engines, sewing machines, pool tables, and gramophones. Canada's 1884 Potlatch Law (rescinded in 1951) outlawed these feasts but succeeded only in repressing them, not in exterminating them.

From the point of view of Northwest Coast people, potlatches sustained the reciprocal relationships among noble houses, including their dependent families. In the northern part of the region "houses" or lineages (often called clans in English) were grouped into pairs, such as Ravens and Wolves, that were expected to alternate as host and guest, thus ensuring a balanced series of feasts and gifts. In the central part of the region guests came from neighboring villages, and marriages between villages gave persons noble titles in both parents' lineages,

creating a more fluid social order. Throughout the Northwest Coast the emphasis was on visibly recognizing rank by the seating order and the amount of the gift. Anthropologists suggest that late nineteenth-century potlatch extravaganzas reflected an increase in consumer goods from Euro-Canadian towns and traders that also brought severe decreases in Indian populations from disease epidemics and political instability.

The Danish ethnologist Kaj Birket-Smith, who worked in Southeast Alaska, hypothesized that ancient contacts around the Pacific spread the institution of “feasts of merit” and publicly marked an investiture in higher status. He pointed out similarities between potlatches and such feasts in Southeast Asia and Polynesia. Through trade across the interior mountains, the potlatch may be related to “giveaways,” held at powwows among Plains First Nations, that stem from the requirement that leaders must be generous. Giveaways are customary at memorial feasts and on such occasions as a child dancing in a powwow for the first time or a person earning a college degree. In both Northwest Coast potlatches and Plains giveaways, new blankets are the standard gift. Especially honored guests are given embroidered robes or star-pattern quilts, lesser acquaintances smaller items, and visitors who have earned the friendship of the hosts may be recognized with gifts of embroidered jackets or other clothing emblematic of the hosts’ style. All guest share in feasting, the gift of food. Potlatches and giveaways share the ethos that giving a gift honors both giver and recipient.

Food at a potlatch must be abundant. Ideally the guests should not be able to finish what is served but should take the surplus home. “Traditional” foods are served, though what is traditional has been modified over time as introduced foods have become standard in the community. Salmon, dried for winter use, has been the prized and usually abundant principal food. Other dishes include berries, seaweed, and meat of mountain goats, elk, moose, bears, seals, small mammals, and halibut, all smoked or dried. Traditionally eulachon, a smelt abundant in early spring, were caught in large quantities and processed into a rich oil used as a sauce at every meal. Potlatches were noteworthy for the lavish outpouring of eulachon “grease,” to the point of ladling gallons into hearth fires until the flames roared to the roof. A description of Tsimshian feasts notes, “The foods that were most valued were those that were scarce, available only seasonally, required intensive labor (and entailed organization by a person of rank), ‘imported items’ (including European foods as they became available), grease, and anything preserved in grease” (Halpin and Seguin, 1990, p. 271).

Dances, both ritual and social, are integral to Northwest Coast potlatches. Elaborately costumed and ingeniously propped dance-dramas, especially those involving a wild cannibal who roared and apparently bit people before the wise elders tamed him, horrified Christian mis-

sionaries. When the Canadian government banned potlatches, First Nations protested that the dancing at potlatches was simply “winter amusement,” like Euro-Canadians’ balls and theatrical entertainments. Furthermore they protested that potlatch feasting provided quality food to their elderly and poor. Most government agents looked away when potlatches were held, recognizing that the First Nations had banned killing slaves and burning houses in favor of conspicuous consumption. By the early twenty-first century potlatches in many Northwest Coast First Nations communities celebrated appropriate occasions without the earlier ostentatious rivalry. Accommodating contemporary employment, twenty-first century potlatches last for a weekend rather than for weeks and are held in community halls. Core practices and foods continue, fostering First Nation identities through public displays of ancient titles, heritage arts, and regional foods.

**POULTRY.** Poultry are domesticated birds raised for food: chickens (including Cornish game hens and poussins), turkeys, ducks, and geese, plus minor species such as squab (young pigeons) and ostrich. Game birds such as quail and Canada geese can also be prepared in much the same ways, although their meat is tougher than that of birds raised on farms. Chickens and ducks are among the most widely distributed food animals in the world and are part of nearly every major cuisine.

Poultry were the last major group of food animals to be domesticated. Humans likely began by raiding the nests of wild birds to steal their eggs, just as nonhuman predators do. Eventually the birds themselves were caught and kept in confinement, or, when thoroughly domesticated, allowed to range around the farmstead or village to find their own food.

## PEKING DUCK

An elaborate method of preparing, cooking, and serving duck was developed by cooks in China's capital city and is known as Peking Duck. The cook will inflate the duck's carcass by blowing air between the skin and the body, blanch the duck in hot water, coat it with malt sugar, and pour boiling water into the cavity. The bird is then hung in a special vertical oven and roasted over a wood fire, preferably using the wood of fruit trees. The result is a bird with a taut golden skin and moist tender meat. Often only the skin is eaten at table, and the meat is sent back to the kitchen to make into other dishes. Or the meat can be cut into thin slices and rolled up in thin pancakes. Elaborate ceremony often attends the slicing of the bird.

Chicken, in particular, has had an increase in popularity in the United States in recent years; according to the U.S. Department of Agriculture, sales climbed from 39 pounds per capita in 1970 to 77 pounds per capita in 2000. The surge in chicken's popularity is attributable partly to its low fat content as compared to beef. Three-and-one-half ounces (one hundred grams) of roasted chicken breast with its skin removed has only 120 calories and 1.5 grams of fat, while the same serving of cooked sirloin steak has 170 calories and 6 grams of fat.

Also propelling chicken toward the center of the nation's plate is its versatility and convenience. Chicken is convenient to prepare and less likely to be ruined by overcooking than the competition. Chicken has become a kitchen favorite for cooks who are both pressed for time and somewhat inexpert at cooking.

Cost is also a major factor in the rise of poultry's popularity. In constant dollars, the wholesale price of a whole chicken dropped 50 percent from 1978 to 2000, while the price of skinless, boneless breast dropped 70 percent.

In contrast to chicken and turkey, duck, goose, squab, and other minor species are expensive and are served mainly on special occasions in the home or in high-end restaurants or restaurants specializing in ethnic cuisine. Peking duck is a mainstay of Chinese cookery, for example.

### Chickens

The most prevalent of the domestic fowl worldwide, the chicken is descended from the Red Jungle Fowl, a bird whose native territory stretches from east India to Malaysia. It is not clear exactly where the bird was first

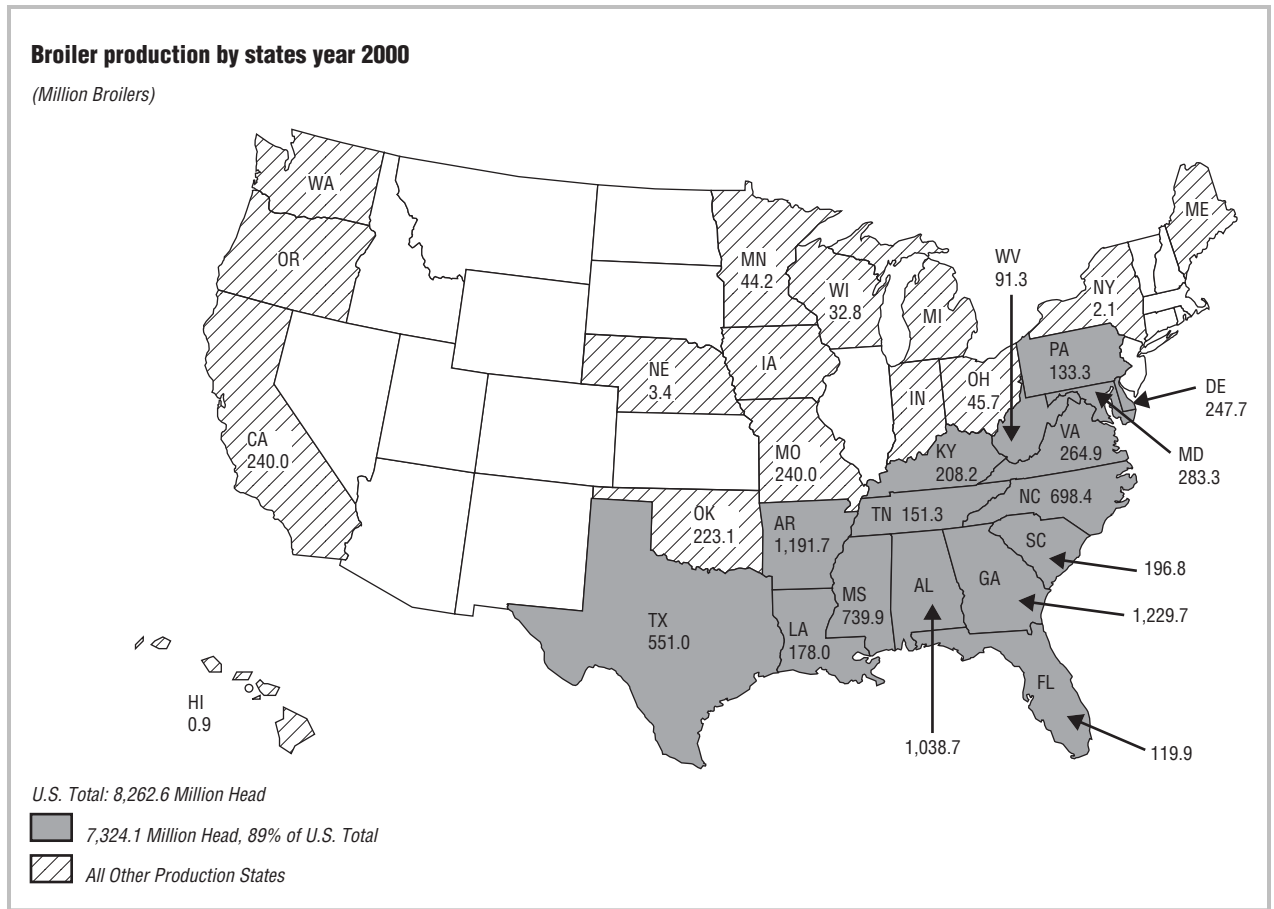

domesticated, but it has been raised by humans throughout its range since ancient times. Polynesian explorers took the chicken across the Pacific as far as Hawaii. Chickens were exported from India to China as early as the fourteenth century B.C.E. and spread to the Near East via the trade routes, and thence to Egypt, Greece, and Rome. Domestic fowl are not mentioned in the Old Testament, but the ancient Egyptians kept fowl and developed large ovens capable of incubating thousands of eggs, indicating that they had large flocks. The Greeks had chickens by the fourth century B.C.E., and many a family in ancient Athens kept a hen to produce eggs. The Romans took up the bird and carried it throughout their empire and beyond; the Germanic and Celtic tribes north of the Roman frontier had chickens before the Christian era. Both Greeks and Romans gave chickens a prominent place in their cuisine and recorded elaborate recipes for cooking them. Poultry shops were so well-established in England by the fourteenth century that their proprietors prevailed upon the authorities to prohibit country people from bringing poultry into the city to sell in the streets in competition with them. Medieval and Renaissance banquets featured chickens along with other fowl: Pope Pius V (d. 1572) gave a banquet that included chicken pie—two chickens to each pie—and spit-roasted quails and pigeons.

A hen in her prime will produce from 100 to 250 eggs per year, a remarkable output for the size of the animal, so the chicken has always been kept more for its egg-laying capability than for its value as meat. Since a hen will lay eggs whether they are fertilized or not, and a single male bird can adequately service a large number of females to ensure reproduction of the flock, most of the male birds are superfluous to an egg-laying flock. They are, however, easily castrated when young, and the resulting birds, known as capons, grow fat and tender. From ancient times until quite recently, capons were the best choice for roasting, with older hens sent to the stew pot. Young male birds, known as cockerels, although smaller than capons, were also available for roasting or other forms of cooking.

Production of birds for their meat has traditionally been a sideline to the egg-laying business. Not until the 1920s were large flocks of chickens raised specifically for their meat, which are called broilers or fryers (the terms are interchangeable). Today about 97 percent of the chicken found in a U.S. supermarket consists of broiler-fryers, with most of the balance consisting of stewing hens (older birds) and a few Cornish game hens. The capon, once a prized dish, is now rare.

The chicken has a short generation span, since the female reaches sexual maturity in about a year. Consequently, the development of different breeds can occur rapidly. Poultry keepers bred birds for desirable characteristics, which traditionally included prolific egg production. The Leghorn is the longtime champion of layers. More recent breeding has emphasized abundant

FIGURE 1

meat production. Specialized breeding companies cross different breeds to attain the right mix of desirable characteristics.

## Turkeys

The wild turkey (*Meleagris gallopavo*) is native to the Americas and inhabited northern Mexico and what is now the eastern United States when Columbus arrived. All of the domesticated turkey breeds descended from this hardy bird, which was domesticated by the Aztecs and other Native Americans. Montezuma himself dined on turkeys, ducks, quails, and other birds, according to a Spanish eyewitness. Early in the sixteenth century, the Spaniards took the bird home, where it began a rapid spread through Europe. People were accustomed to eating large birds—swans and peacocks had graced noble tables since ancient times—and the turkey provided an abundance of meat. In this respect, the turkey was very different from the chicken, since the turkey has been prized chiefly as a source of meat rather than eggs.

The name given the bird by Europeans reflected mass confusion about its origins and perhaps a similarity to another bird, the guinea fowl, which had recently been

reintroduced into Europe after an absence dating to the fall of Rome. The guinea fowl was called an “India chicken” by many, apparently because it reached Europe from the east and was thought to have originated in India, although in fact it is from Africa. When the turkey showed up, it looked like a bigger version of the same bird and was dubbed the “bird of India” in nearly every language: “coq d’Inde,” cock of India (later *dinde*), in French, “indianische Henn” in German, and variations on the same in other European languages. Eventually the turkey took sole possession of the “India” name and the guinea fowl was renamed after the Gulf of Guinea in west Africa. The only major exception was England, where the bird was called the “turkie cock” (or hen). This may reflect a belief that the bird came from Turkey, since many exotic products, edible and otherwise, had passed through the eastern Mediterranean on their way to western Europe. A more specific theory is based on the fact that English trade to that region was dominated by the Company of Merchant Adventurers Trading to the Levant, popularly known as the Turkey Merchants. Officers of the company reportedly stopped in Spain and picked up some of the birds on their way back to England, and the bird was named after them.

TABLE 1

**Production of poultry meat and eggs, leading nations, 2001**

In metric tons

Nation	Poultry meat	Chicken meat	Turkey meat	Duck meat	Goose meat	Primary eggs*
<b>WORLD</b>	<b>70,358,813</b>	<b>60,258,645</b>	<b>5,085,889</b>	<b>2,936,687</b>	<b>2,058,969</b>	<b>56,594,078</b>

\*Table eggs of all species, including chicken, duck, and goose.

Neg.: Negligible production

The production of poultry meat and eggs constitutes a large industry worldwide. Nearly every country produces chicken meat and eggs; turkey is popular largely in Europe, North America, and Brazil; duck meat production is found largely in China and Europe; and goose meat is largely Chinese. The United States is the leading producer of poultry products, particularly chicken (14 million metric tons produced in 2001) and turkey (two and a half million tons), in both of which it leads the world. China is second in chicken production with about nine million tons, and dominates the world in goose meat and duck meat production. In fact, 91 percent of all the goose meat produced in the world, and 68 percent of the duck meat, is produced in China.

Other major countries in chicken meat production include Brazil, France, Mexico, the United Kingdom, and Thailand, while the leading turkey producers after the United States are France, Germany, Italy, the United Kingdom, Brazil, Canada, and Hungary. France and Thailand are the leading duck meat producers after China, followed by Viet Nam, the United States, Malaysia, the Republic of Korea and the United Kingdom. The goose meat industry is very small outside China, with the biggest countries being Hungary, Egypt, Madagascar, and Poland.

China produces more than 23 million metric tons of eggs, or more than forty percent of the world's supply, which includes goose and duck eggs as well as chicken eggs. The United States is next with five million tons, followed by Japan with two-and-a-half million tons and Russia, India, and Mexico with about two million tons each. Japan is the leading consumer of eggs on a per capita basis, with China in second place. In the United States, per capita egg consumption has dropped in recent years, largely in response to concern about the cholesterol content of eggs.

SOURCE: United Nations Food and Agriculture Organization Statistical Databases; U.S. Department of Agriculture Foreign Agriculture Service.

Whatever the reason for its odd name, the turkey seems to have taken Europe by storm. It arrived in Spain around 1524, was mentioned by Rabelais in 1548, and was served at a royal wedding feast in France in 1570. In England, the bird was established even sooner, being mentioned in the sumptuary laws of 1541. Turkeys could be raised by peasants and by the turn of the seventeenth century were being husbanded throughout Europe. The Pilgrims recognized the local turkeys when they settled in Massachusetts and learned that the Native American name for the bird was amazingly close to their own. The natives called it a "furkee."

### Ducks and Geese

Ducks and geese are distributed worldwide and were trapped and domesticated by humans in antiquity for both eggs—especially duck eggs—and their meat. Ducks were probably domesticated before geese, and both were certainly domesticated in most of the world long before chickens. Ducks were raised in China two thousand years B.C.E. The Incas of Peru kept ducks, and the Spanish brought home what became known as the Muscovy duck (continuing the tradition of naming birds for lands far from their own).

Ancient peoples in Europe and Asia tamed mallard ducks, which were the foundation of most breeds of domestic duck, such as the Pekin (or Peking) of China, the Aylesbury of England, and the Rouen of France. Most ducks consumed are slaughtered at a young age and thus termed ducklings; mature ducks are tough and are used mainly in processed products.

In the United States, modern production began when a clipper ship brought three Pekin ducks and a drake from China in 1873. All of today's Pekins are direct descendents of these pioneers. Strains of the Pekin were used to produce the Long Island Duckling, which became the most desirable breed. Production of these birds in the United States eventually moved largely to the Midwest, but only birds actually raised on Long Island for at least seven days and processed there may be labeled "Long Island Duckling." Birds that are otherwise essentially identical, but raised in Indiana or other states, are labeled "White Pekin Duckling."

Regardless of where it is raised, the White Pekin is a tender and juicy bird and is the most popular choice for the table. The Muscovy has a stronger flavor than the White Pekin. The White Pekin and the Muscovy have

been crossed to produce the Moulard, which is raised mainly for the sake of its liver for *foie gras*. (*Foie gras* is a delicacy consisting of duck or goose liver that has been enlarged to many times its normal size by excessive feeding of the birds. In Europe, where goose is preferred, the bird is “crammed” with feed through a funnel put down its throat. [See photo on page 127.] In the United States, ducks are encouraged to overeat but are not crammed.) The familiar, green-headed Mallard is both raised on farms and hunted in its wild state. It is smaller and tougher than the White Pekin and tends to be quite greasy. Ducks are considered “red-meat” birds, and the breast meat when fully cooked will be pink, which in chickens and turkeys would be a sign of undercooking.

Geese have been domesticated since ancient times in many parts of the world, but the Greylag goose of Europe, which is still found in the wild, is the ancestor of most of the domesticated breeds in existence today. The all-white Emden and the all-gray Toulouse are the two most popular breeds in the United States today; many African and White Chinese are also raised. The Chinese goose is descended from the swan goose of Asia rather than from the Greylag.

Goose production is a small industry in the United States, representing only two-tenths of 1 percent of poultry production, and might virtually disappear were it not for the fact that geese also produce down, which is much in demand for its insulating properties. Down is used in ski jackets, comforters, pillows, sleeping bags, and other cold-weather gear.

Both Greeks and Egyptians kept geese and crammed them with grain to fatten them and enlarge their livers. The Romans apparently adopted geese from the Gauls; Pliny wrote of flocks of geese being driven to Rome from what is now Picardy. The goose was the most prized domestic fowl in Europe for hundreds of years after the heyday of Rome, and the Gauls and their descendants, the French, became the acknowledged masters of the art of creating *foie gras* by force-feeding the birds. The goose became a holiday bird in much of Europe and is considered an alternative to the turkey in the United States. The meat is all dark and has the consistency of roast beef when properly cooked.

## Squab

Squabs are young pigeons that have never flown, usually slaughtered at four weeks old. If a squab is slaughtered much after four weeks or after it has begun to fly, the muscles will have hardened and the meat will not be as tender as when the bird was in the nest.

Pigeons are widely spread around the world and have been raised for their meat since antiquity. Pigeon keeping was widespread in ancient Egypt; by the first century B.C.E., dovecotes with one thousand nesting places were common. The design of the dovecotes, using earthen jars as nesting places, survived into modern times. Twenty

thousand pigeons were served as a feast given by an Assyrian king in the ninth century B.C.E. Pigeons were popular in ancient Greece, Rome, and during medieval times.

Squab is considered a delicacy around the world today. In the United States, squabs are available mainly through specialty food shops or in ethnic and high-end restaurants.

## Production and Life Cycle

All the major forms of poultry are produced in similar although not identical systems. The model in the United States is the highly efficient broiler chicken sector, which produces the vast majority of the poultry products consumed by Americans. Turkeys and other forms of poultry are raised under conditions that are similar to those of chickens.

The chicken industry was localized, with entrepreneurs buying surplus chickens from egg operations and backyard flocks for the city markets, until early in the twentieth century, when more organized, long-distance shipping of live poultry commenced. New York and other cities received rail cars of live birds that were distributed to butcher shops or slaughtered and dressed at processing plants for distribution. In the 1920s, farmers discovered that large flocks of chickens could be raised specifically for their value as meat. These farmers needed regular batches of chicks, supplied by large-scale hatcheries, and feed, which they got from commercial feed mills. The hatcheries and mills typically had better access to capital and marketing channels than farmers, and they formed the core of the all-purpose companies that dominate the business today. In the mature industry, a single company typically handles the entire life cycle of a bird, including hatching, feed formulation and production, processing, and marketing. This business model is known as “vertical integration,” and there are about fifty such companies in existence in the United States (as of 2001). Breeding of the animals for desirable characteristics is handled by either the integrated company itself or by one of a several specialized breeding companies. Once hatched, the birds are typically taken to privately owned farms, where they are raised to market weight by farmers working under contract to the company.

Production of turkeys is somewhat less centralized than the chicken business, although the turkey industry has been moving in the direction of greater integration. The duck industry is very similar to the chicken model. Most of the squabs in the country are processed and marketed by a cooperative. The goose industry is small and integrated.

## Life Cycle

The life cycle of a broiler begins with a specialized breeding flocks, where roosters and hens produce fertile eggs that are collected every day and taken to a hatchery, where thousands of eggs are kept in each incubator under carefully controlled conditions of temperature and

Guinea fowl from a detail of a mosaic floor in the house of Eustolios, Kourion, Cyprus, circa 300 C.E. PHOTO WILLIAM WOYS WEAVER.

humidity. The chicks hatch out on the twenty-first day and are taken to the farm where they will be raised for six to seven weeks. The typical growout facility is a barn-like, one-story structure about forty feet wide and four hundred feet long, which contains about twenty thousand birds. The trend in recent years has been to even larger houses holding up to thirty-three thousand birds. The birds have the run of the building, as cages are not used in broiler production.

Feed is made largely from corn and soybeans with the addition of animal fats for energy, animal protein, amino acids, minerals, and vitamins. Chickens eat almost continuously, pausing to digest each meal before going back to the feeder for more.

When the birds reach market weight of about five and a half pounds, they are collected and taken to the processing plant where they are stunned, killed, defeathered, eviscerated, inspected for wholesomeness by personnel of the U.S. Department of Agriculture, chilled, and either packed for shipment or, more typically, sent to another plant to be cut into pieces, deboned, and processed into a wide variety of products. The finished weight of a whole bird is usually about three and a half pounds, with birds destined for the fast-food market being typically smaller than birds being sold at retail.

### Marketing

Poultry companies market their products through supermarket chains, restaurant chains, and independent distributors. The process is highly organized and efficient. Unlike red meat, in which an in-store butcher handles

the final cutup, poultry is usually packaged at the plant and shipped to stores ready for sale, with computerized scales at the processing plant weighing the packages and applying the price set by the retailer.

Approximately half the chicken consumed in the country is sold through supermarkets and other retail outlets while half is sold through fast food and other restaurants, cafeteria, and other food service outlets.

### Poultry Health

Chickens and other poultry are subject to a wide variety of diseases whether they are kept indoors or not. They are normally vaccinated against certain diseases while they are still in the egg and then again as chicks. One of the most prevalent problems is colonization of the chicken's gut by microscopic, parasitic animals known as coccidia. Most producers, even "organic" or "free range" ones, add chemical compounds to the chicken feed to control coccidia. Poultry flocks are monitored by the farmer and by company representatives for signs of other diseases, which, if they begin to claim more than a certain number of victims, will be treated with antibiotics administered through the feed or water. Some antibiotics, when used in the feed at low levels over a period of time, also result in measurable increases in the bird's weight. The exact mechanism for this "growth promotion" is not known, but poultry experts believe that the antibiotics eliminate organisms in the chicken's gut that would otherwise compete for nutrition. The practice of using antibiotics for purposes other than treating disease is somewhat controversial, and some experts in human health object to it on the grounds that low-level use of antibiotics, some of which are also used in human medicine, can promote the rise of bacteria that are resistant to the drugs. These can be passed to humans either on food products or by entering the environment and could create infections in humans that could be resistant to antibiotic therapy. The National Research Council has found that "there is a link" between the use of antibiotics in food animals and antibiotic resistant infections in humans and recommended further study.

### Hormones

Federal law prohibits producers of chickens and other poultry from giving artificial or added hormones to their animals. Producers are allowed to give only those pharmaceuticals or additives that are on the Food and Drug Administration's approved list, and there are no hormones on the list for chickens or other poultry raised for their meat. It would be impractical to give hormones anyway, since they cannot be given in the feed and have to be repeatedly injected as the animal grows, virtually an impossibility in a flock of twenty thousand birds or more.

### Alternative Production and Processing Systems

Some have criticized the mainstream industry for its style of mass production, confinement of the animals, and use

of antibiotics. The “free range” style of production is intended to address these concerns. In a “free range” system, the birds have access to a pen outside the growout house. Some producers provide a pen as large as the growout house itself, while others provide a much smaller fenced area. The pen gives the chickens the opportunity for exercise, sunlight, and fresh air. Chickens will not necessarily take advantage of the opportunity, however, if the food and water are located only inside the house. Many “free-range” birds thus do little actual ranging.

Since chickens will peck at anything in search of food, a small pen can be quickly denuded of vegetation. Some small-scale producers address this problem by confining the chickens in a covered, portable pen that is moved each day to a different plot of grass; this is called “pastured poultry.” Few if any producers will actually turn chickens loose to fend for themselves, although some turkey producers will do so in an area in which forage is available, such as an orchard, in which the turkeys can feed on fallen fruit. “Free range” chickens generally cost considerably more than standard chickens, and they represent only a small portion of total production—probably less than 1 percent.

“Organic” production is another attempt to differentiate the product from those of large-scale producers. The term was used for years on a wide variety of food products without a consistent nationwide definition. The U.S. Department of Agriculture promulgated regulations in 2000, to take effect in 2002, which prohibit the use of the term “organic” unless the production and processing of the product is consistent with the regulation. A qualifying product can carry a “USDA Organic” label. Poultry labeled “organic” must be raised on feed made from organically grown grain that cannot contain animal by-products; cannot be given antibiotics or anti-parasitics; and must be given access to the outdoors, among other requirements.

### **Kosher Processing and Specialized Labeling**

“Free range” and “gourmet” chickens are processed in a manner that is essentially identical to standard chickens and are killed by high-speed mechanical devices. Kosher chickens, however, are slaughtered manually by rabbis, not by machine, and are soaked in salt water to draw out the remaining blood to meet the requirements of Jewish law. As a result, Kosher chickens are generally more expensive than standard birds.

In France, the national ministry of agriculture and fisheries operates a program called the “Label Rouge,” or “Red Label,” which is intended to recognize higher-quality products. Products bearing the red label must employ more traditional methods of production than more standardized products. France offers the red label to qualifying producers of chicken, guinea fowl, turkey, capons, duck, and geese, as well as other animals.

### **Symbolism**

Poultry has long figured in human symbolism and legend. Geese supposedly saved ancient Rome from a surprise attack in the fourth century B.C.E. by cackling loudly when the invaders tried to sneak up on the Capitol. Pigeons were offered as sacrifices by the Hebrews of the Bible. The sixteenth-century Flemish artist Pieter Bruegel the Elder—a great fan of fantastic-looking animals—used the turkey as a symbol of envy in his series of paintings on the seven deadly sins. But the domestic fowl most often used as a symbol is the ordinary chicken.

In ancient Greece, chickens were offered in sacrifice to the god of medicine, Aesculapius, to protect against disease, to thank the god for recovery, or to prepare for imminent death. Aristotle conducted the first known systematic study of embryology by opening hen’s eggs at each day of incubation. Less scientific ancients used the birds for magic, sorcery, and divination.

The chicken has always been one of the most familiar domesticated animals since almost any family could afford to keep a hen, and chickens were kept in the city as well as the countryside. Humans therefore had abundant opportunity to observe the chicken at close range. They could hardly help but notice the insatiable sexual appetite of the male bird, which can copulate up to thirty times a day in his prime. The traditional term for the rooster—the cock—was given in slang to the male sexual organ, and the upright, strutting posture of the male, and his domineering behavior toward the females, seemed to symbolize traditional male supremacy.

The rooster’s habit of crowing loudly at dawn has made it for centuries the symbol of awakening. The most famous example is the prediction by Jesus of Nazareth that his chief apostle, Simon Peter, would deny knowing him three times before the cock crowed twice. When Peter heard the crowing and realized the prediction had come true, “he went out and wept bitterly.” The rooster’s role as a herald has continued to this day. A rooster figures prominently in a tapestry hanging in the United Nations headquarters in New York that commemorates the Chernobyl nuclear power plant disaster, presumably as a symbol of the world’s need to awaken to the danger of uncontrolled technology.

### **Food Safety**

Chickens, turkeys, and other types of poultry are produced on farms and processed in clean but not sterile plants, so their meat can carry microorganisms that potentially harmful to humans. For example, approximately 10 percent of raw chickens carry *Salmonella*, which can cause illness and even death in humans. Improved processing technology and stricter government regulations have improved the situation considerably in recent years, but consumers should always handle raw meat and poultry with care.

To ensure that poultry products are safe to eat and to avoid contaminating other foods with the bacteria that

may be carried on raw poultry, the cook should keep four basic points in mind:

1. **Clean:** Keep working surfaces clean. Wash cutting boards after cutting raw poultry and before using them for other foods, such as vegetables. Wash the hands before touching other foods. Wash utensils in hot, soapy water.
2. **Cook:** Cook foods to the recommend temperature. Proper cooking deactivates bacteria and renders the food safe to eat.
3. **Chill:** Bacteria such as *Salmonella* do not grow well at cold temperatures, so prompt refrigeration at 40°F or below will help control the growth of bacteria on raw foods. After poultry is cooked, in order to control the growth of molds, yeasts, and spoilage organisms, it should not be left out at room temperature for more than two hours. *Listeria* is an exception to the rule, however, since it will grow at refrigerator temperatures. *Listeria* is sometimes found on products that were cooked at the plant, such as hot dogs and lunch meat. Vulnerable individuals—chiefly pregnant women, small children, the elderly, and immuno-compromised people—should reheat such foods until they are steaming hot before consuming them to eliminate the risk of *Listeria* contamination.
4. **Avoid cross-contamination:** Poultry juice can contain millions of bacterial cells. Prevent poultry juice from dripping onto other foods by overwrapping the packages if necessary in plastic wrap.

## Selection

Poultry comes in a dizzying array of forms ranging from a package of chicken wings weighing two ounces each to whole turkey weighing twenty pounds or more. The consumer can buy products based on specific meal plans or based on cost consideration, for example, stocking up on boneless chicken breast when it is on sale. In determining quantities, keep in mind that the edible yield from boneless products is far greater than from bone-in; in fact, while boneless chicken costs considerably more than bone-in, the price difference almost disappears when the bones are excluded. On the other hand, much of the weight of ducks and geese consists of fat that will drain off when the bird is cooked. As a rule of thumb, four ounces of skinless, boneless chicken will serve one adult, while a whole chicken will serve approximately one person per pound. For a whole turkey, figure on one pound per person. A whole duck or goose, which has less meat, bigger bones, and more fat than turkey, will serve three persons, or four if there are enough side dishes, while one squab is an individual serving.

## Classes of Chickens

Chickens are classified primarily by the size, weight, and age of the bird when processed. Chickens are produced

to meet specific requirements of the customer, which can be a retail outlet, fast food chain, or institutional buyer, among others. The weights given here are “ready to cook,” that is, eviscerated or “dressed.”

**Broiler**—Chicken raised for meat products; of either sex; usually six to seven weeks old; often labeled “tender young chicken.”

**Poussin**—Less than twenty-four days of age and about one pound or less.

**Cornish Game Hen**—Less than thirty days of age and about two pounds.

**Fast-food Size Broiler**—two pounds four ounces to three pounds two ounces, (mostly two pounds six ounces to two pounds fourteen ounces), usually cut-up, without necks and giblets, may have tail and leaf fat removed, and less than forty-two days of age.

**3's and Up**—three to four and three-quarter pounds, usually with neck and giblets for retail grocery; whole, cut-up, parts, and forty to forty-five days of age. Typical retail size.

**Broiler Roaster**—five to six pounds, hens usually fifty-five days of age.

**Broilers for Deboning**—five to six pounds, males usually forty-seven to fifty-six days of age. Deboned for nuggets, patties, strips, and similar boneless products.

**Heavy Young Broiler Roaster**—six to eight pounds, sold fresh or frozen through retail grocery, both whole and parts, less than ten weeks of age. Typical “roaster.”

**Capon**—Castrated male broilers weighing seven to nine pounds, and about fourteen to fifteen weeks of age. Considered to be very flavorful.

**Stewing Hen or Heavy Hen**—breeder hens that are no longer commercially productive for laying hatching eggs, usually five to five-and-one-half pounds, about fifteen months of age, used for cooked, diced, or pulled meat. Sometimes sold whole at retail for use in homemade soup. While tougher than younger birds, the stewing hen has developed a deeper flavor.

## Turkey

The male bird, or “tom,” tends to be bigger than the hen, although there is no noticeable difference between the two in the quality of their meat. Almost all the turkeys in the supermarket are young turkeys, slaughtered at about fourteen weeks of age for hens and eighteen weeks for toms.

Turkey breast is even leaner than chicken and is very widely used in sandwich meat and other delicatessen-type products, as well as sold fresh in the meat case. Turkey dark meat is also widely used in hot dogs, bologna, and other processed meat products. Whole birds are available year round but are especially popular as the main course at Thanksgiving and Christmas. Turkey parts are in-

creasingly popular both year round and at the holidays: whole or half breasts, tenderloins, and legs.

### Storage

Poultry is generally sold with a “sell-by” date on the package, which, for chicken, is typically ten to fourteen days from processing. Poultry should be cooked or frozen within a few days of purchase to maintain its quality. Fresh poultry should be kept in its original wrapping and stored in the coldest part of the refrigerator. If the package is leaking fluid, it should be overwrapped with plastic or aluminum foil.

Frozen poultry will keep six months or more in the freezer set at 0°F. Frozen whole birds or parts can be defrosted in the refrigerator, which can take twenty-four hours or more, or in cold water, which should be kept running or changed every 30 minutes. A whole turkey should be defrosted in water because defrosting in the refrigerator takes too long. Whole chickens and all types of parts can be defrosted in the microwave, but a very low power setting should be used and caution exercised to ensure that the product does not begin to cook during the defrosting.

### A Note on Doneness.

Poultry parts reach the desired state of doneness at different internal temperatures. Boneless chicken breast cooked on an outdoor grill can be cooked without reaching 150°F (even though 160°F is usually given as the minimum temperature that breast meat should reach). Yet drumsticks, because of their dark meat and higher fat content, will not be done until they register 180°F. Bones conduct heat, so when taking the temperature of a part or a whole bird, do not let the thermometer rest against a bone.

Generally, boneless white meat such as chicken or turkey breast should be cooked to 160°F, bone-in parts usually need to reach 170°F; and dark meat should hit 180°F.

Poultry will usually be safe to eat before it is done. Any food is safe to eat at 160°F because bacteria are destroyed at temperatures over 140°F. One exception: it is impossible to make spoiled food safe to eat by heating it because spoilage organisms create toxins; even if the bacteria are destroyed, the toxins remain. Spoiled food cannot be fixed by cooking and must be discarded.

### Methods of Preparation: Chicken

As befits its reputation as the most versatile of meats, chicken can be prepared in a host of different ways. Here are the principal methods of preparation and the chicken products most appropriate for them.

**Roasting.** A whole roast chicken is a magnificent sight, browned to perfection and rich in the promise of tender, juicy meat. Because of its small size relative, say, to a turkey, roasting a chicken takes only a couple of hours

Tin bird roaster for open hearth cooking. England, ca. 1860. Small birds such as squab were suspended from hooks inside the bonnet. ROUGHWOOD COLLECTION. PHOTO CHEW & COMPANY.

and is perfect for a Sunday afternoon dinner. Be sure to remove the giblets (heart and liver) from the cavity if present and discard unless you intend to make gravy with them. The chicken may be stuffed with any type of bread-based stuffing, although this increases cooking time. Some experts recommend cooking the stuffing in a sauce on the stove. To ensure even cooking and present a tidy appearance in the finished product, it is best to truss the chicken, that is, to use kitchen string or other clean white string to tie its legs over the cavity and secure its wings to the body.

Preheat the oven to 325°F and place the chicken on a rack in a roasting pan or a deep baking dish. Use of the rack will keep the chicken from sitting in its own grease.

Roast for about an hour, basting occasionally with the pan juices. The chicken is done when the internal temperature reaches 180°F on a thermometer inserted deep into the thigh without touching bone. Let stand 20 minutes to allow the juices to settle before carving.

**Baking.** Roasting and baking are essentially the same thing, the difference merely being that a whole chicken is roasted while parts are baked. Any poultry part can be baked, but the method is most appropriate for legs, thigh, and drumsticks. Preheat the oven to 400°F, place the chicken part in a lightly oiled roasting pan or in a deep baking dish, and place in the oven for 40 to 45 minutes. Use of a rack will help keep dark meat parts from picking up too much melted fat; it is not necessary for breast meat.

**Broiling.** In broiling, meats are placed several inches under the heat. This works well for all chicken parts, but especially for boneless or bone-in breasts. Preheat the

broiler and broil the breasts for approximately 15 minutes per side. Bone-in breasts are placed six to eight inches from the heat; boneless breast lie flat and can be placed closer. Cook the rib side of bone-in breasts, or the rough side of boneless breasts, first, and then finish with the skin side of skin-on breasts or the smooth side of skinless, boneless breasts.

**Sauté.** Boneless parts such as breast or thigh can be cooked in a pan on top of the stove in a little liquid, which can be chicken stock, wine, butter, olive oil, or some combination. The trick is to brown the chicken on both sides before reducing the heat to cook it through. Boneless breast cooked in butter and olive oil and seasoned with lemon and rosemary is a delicious dish. It can be made even more delicate by slicing the breast portion in two with the knife held parallel to the counter, resulting in two breast fillets. A thin piece of breast will cook in just a few minutes on each side.

**Fried.** Fried chicken is a mainstay of southern cooking, although Southerners clearly did not invent it; a cookbook published in England in the eighteenth century included a recipe for fried chicken that could be used today. Fried chicken has fallen somewhat into disfavor, along with many other types of fried foods, due to its fat content and reputation for clogging arteries. However, the best fried chicken is not greasy and does not have exceptionally high added fat. The key seems to be to keep the frying oil very hot so that the skin of the chicken is sealed quickly, thus keeping the liquid fat out of the meat. Oil tends to lose its frying ability with use, so either start with plenty or keep heating up new batches of oil. Drumsticks and wings are the parts traditionally considered most suited to frying, but breasts and thighs will do just as well.

Southern cooks often recommend soaking the raw chicken in buttermilk and refrigerating for several hours. Then let the excess milk drain off, dredge the chicken parts in seasoned flour, and dunk into hot oil in a deep pan or heavy skillet. Many a cook has found the skillet lid a handy shield against spattering grease. Keep the oil at about 350°F until all the parts are added, then reduce the temperature to around 320°F and cook 10 to 12 minutes per side or until the juices run clear. (Five minutes per side for boneless breast.) The chicken is done when it turns golden brown. Drain on paper towels to get rid of as much grease as possible.

When frying wings, split them at the joints and discard the outermost and least meaty part, which is known as the “flapper.” The meaty first joint is known as the “drumette.” Wing portions make excellent appetizers.

**Soups and stews.** The stewpot was traditionally the destination of older and tougher birds that needed long, slow cooking to make them tender enough to eat. Old, tough birds are hard to find these days, although the chicken companies will sometimes market played-out hens in the

dead of winter precisely for this purpose. Newer soup recipes, such as those based on Asian dishes, are light and delicate and perfectly suited to the young and tender birds that dominate the market.

**Grilled.** Chicken has ridden the wave of popularity of both outdoor and indoor grilling in recent years. Dark meat in particular, such as legs and thighs, stand up well to the intense heat of grilling because of its higher fat content and the presence of collagen, which melts and keeps the meat moist. Breasts should be marinated to keep them moist during grilling and will cook in no more than 15 minutes per side. Boneless breast will cook in about 6 minutes per side. Strong favors such as vinegar and soy sauce can be used with chicken bound for the grill. The grill itself should be brushed or rubbed with oil to keep white meat from sticking to it. If barbecue sauce is used, save it until you have turned the chicken skin side up.

## Turkey

Norman Rockwell knew his business when he chose a roast turkey as the symbol of abundance in his painting called *Freedom from Want*. There is nothing more American than the Thanksgiving turkey.

**Roasting.** Roasting a turkey can be a trying experience, especially one that tips the scales in excess of twenty pounds. It is hard to get the dark meat cooked through without overcooking the breast. One approach is to eliminate the dark meat entirely and buy a turkey breast (or two if the whole family is coming). The all-white meat breast is easily cooked according to the package directions, usually in a 350°F oven. If there are dark meat fans in the crowd or if cooking anything less than a whole bird seems somehow un-American, then satisfactory results can be obtained by roasting the bird at 325°F for 10 to 12 minutes per pound, shielding the breast with aluminum foil for the first hour, and continuing to cook until a meat thermometer registers 180°F when inserted into the deepest part of the thigh without touching bone. If the bird is stuffed, the stuffing must reach 160°F to ensure safety. Basting the breast with melted butter can help it stay moist. Another trick is to lay raw strips of bacon over the breast, letting the bacon release its fat to the breast as it crisps. Many turkey processors provide “self-basting” birds, which are injected at the plant with oil to maintain their moistness. If you do not have a thermometer, the pop-up thermometers inserted at the plant are generally reliable. Or you can wiggle the legs and wings to see if they move freely, or insert a knife or fork into the bird to see if the juices run clear. Let the bird sit for 20 minutes after coming out of the oven before trying to carve it. And give yourself plenty of time—an eighteen-pound bird that goes into the oven after breakfast will not be ready until early to mid-afternoon.

Turkeys are sold both fresh and frozen. It is a matter of opinion whether one tastes better than the other.

One thing is certain, however—a fresh turkey will not have to be defrosted, which can be a difficult and time-consuming process. Just keep a fresh bird in the refrigerator until you are preheating the oven, when you can take it out, rinse it off, remove the neck and giblets from the cavity, and pat it dry. A frozen turkey should be placed in a clean sink or large pan and defrosted under cold running water. It takes several hours to defrost a large, solidly frozen turkey.

**Grill.** Turkey thighs and drumsticks can be grilled just like chicken parts. So can turkey cutlets, which are slices of skinless, boneless turkey breast. Turkey breast is the lowest in fat of all the cuts of poultry, however, so breast meat should be marinated or brushed with oil before being subjected to the heat of grilling.

**Sauté.** Cutlets sliced very thinly are called turkey scaloppini, and they lend themselves very well to being sautéed in a pan and finished with a flavorful sauce.

**Other turkey products.** Turkey is a major factor in the delicatessen counter, with turkey rolls providing lunch meat and the dark meat used very extensively in frankfurters and other already-cooked products. Since breast meat tends to be quite dry, processors form breast meat into rolls and inject them with a saline solution to keep the meat moist and easily carved. Ground turkey is a popular substitute for ground beef in many recipes due to its lower fat content, and turkey is turning up in sausages and other products as processors continue to try to get away from relying on holiday sales to carry them through the year.

### Squab

Squab can be roasted, broiled or grilled. The bird weighs only about one pound and will cook quickly whichever method is used. The key is to cook the bird only until the breast meat is medium-rare, with the juices still running pink and the meat still juicy and pinkish. Broiled squab should be turned once and will cook in 15 to 20 minutes. If grilling squab, start with the skin side down to melt the fat under the skin. If grilling is desired, it is best to buy boneless squab and also discard the wings so that the bird will lie flat on the grill. Boneless squab can also be sautéed in a pan.

### Cornish Game Hens and Poussins

Cornish game hens and poussins are simply small chickens. They are generally intended to be served whole, or, at most, split in two (although these birds, like other chickens, are marketed in larger sizes than they used to be). They can be roasted at 350°F for 25 to 40 minutes, depending on size. They can also be broiled with the backbone removed so the split bird lies flat on the broiling pan.

### Duck

Duck is all dark meat; the breast tastes more like turkey drumstick than it does like chicken breast. Smoked duck,

Poultry farmer in Alsace force-feeding a goose in order to fatten the liver for pâté. This feeding method is not legal in the United States. Photo circa 1900. ROUGHWOOD COLLECTION.

when sliced, is easily mistaken for roast beef. The challenge in cooking duck is that the bird has quite a lot of fat and it is difficult to end up with meat that is moist but not greasy from the melting fat and skin that is crisp and flavorful instead of rubbery. High heat would help get rid of the fat while crisping the skin, but the fat melts quickly and begins to smoke. The cook can find the kitchen full of smoke and can even have a fire in the oven if the rendering process is not controlled.

Two methods are generally successful in rendering the fat while crisping the skin. The first involves medium heat while the second involves steam as well as dry heat.

**Roasting.** Prick the skin with the tip of a paring knife, being careful to pierce the fat layer without breaking the skin. This will help drain off the fat during cooking. Roast

the bird in a 350°F oven, breast side up on a rack in a roasting pan, for one hour and fifteen minutes. Drain the fat out of the roasting pan and roast for 40 additional minutes at 350°F and then 15 minutes at 500°F to crisp the skin.

**Twice-cooked.** Chinese cooks use a different method to get rid of the fat and produce a crisp skin. With skin pricked as in the basic roasting directions, the duck is placed on a rack in a roasting pan with half an inch of boiling water in the bottom. The pan is covered and placed over heat to keep the water simmering for about an hour, until the skin pulls away from the wing joints, exposing the meat. The bird is then cooled to room temperature, brushed with soy sauce or other seasonings, and roasted in a 400°F oven for 30 to 40 minutes, or until crisp. For an even crisper skin, rub the raw bird with salt and allow it to dry in the air in the refrigerator for several hours before cooking.

**Broiled.** Duck parts can also be broiled, although the fat released by the parts can smoke and even catch fire. Remove as much visible fat as possible before placing the parts in a broiling pan four inches from the preheated broiler. Broil 30 to 45 minutes or until golden brown. Drain off fat as it accumulates or sprinkle the melted fat with salt to reduce the chance of fire.

### Goose

Goose is typically purchased and cooked whole. The meat is even darker than duck and, when cooked, resembles fully cooked roast beef. The goose is also even fattier than the duck, since it has an even thicker layer of fat under the skin. Dry heat works better than steam to render the fat and produce a crisp skin.

Prick the skin all over with the point of a paring knife, being careful not to pierce the skin. Roast for one and a half hours, breast side down, in a 325°F oven. Remove from the oven and pour off the grease. Return to the oven and roast for another one and a quarter to one and a half hours until the skin has puffed up around the breastbone. Turn the oven up to 400°F, remove the goose from the oven and transfer, with rack, to a clean pan and roast for another 15 minutes until the skin is crisp. Let stand 30 minutes before carving.

### Ostrich and Emu

Ostrich and emu are birds originally from southern Africa and Australia, respectively. The ostrich is the largest bird species and can reach eight feet in height. The emu is the second biggest bird species and tops out around six feet. Ostriches were formerly raised for their feathers, which were greatly prized for use in women's hats. When long feathers went out of fashion, the industry collapsed. It has revived in recent years, however, because of an interest in ostrich meat, which has very little fat or cholesterol. Both birds have deep red meat which reminds many people of venison. The meat can be sauteed or grilled

and should be cooked only to medium-rare, since overcooking leaves the meat tough and dry.

**POVERTY.** About 31.1 million, or 11.3 percent, of Americans were poor in 2000. "Poor," as used here, means living below the poverty threshold, a dollar amount determined by the United States Bureau of the Census by taking a family's total income before taxes and then adjusting for the size of the family and the number of related children under eighteen years of age. In 2000, the poverty threshold ranged from \$8,259 for an individual sixty-five and older to \$33,291 for a family of nine

or more individuals, including eight or more related children under eighteen. The poverty threshold for a family of two adults and two related children was \$17,463. Individuals sixty-five and older, blacks and Hispanics, people in families with no workers, households headed by women, and people living inside central cities suffered disproportionately higher rates of poverty compared with other Americans.

The federal poverty threshold originated in the 1950s and is based today on the cost of the Thrifty Food Plan, a minimal-cost food plan determined to be nutritionally adequate according to national dietary guidelines, its cost multiplied by a factor of three (based on the assumption that nutritionally adequate food will cost one-third of a family's income) to account for other living expenses. Although it is updated annually according to the Consumer Price Index for inflation, a chief criticism of the poverty threshold is that food expenses have accounted for less than 15 percent of average income since 1965 (10.2 percent in 2000), making the multiplier too small, while other living expenses (such as housing, health care, transportation, and child care) have increased dramatically, especially for the poor.

Quantitative descriptions of the food and nutrient intakes of poor Americans can be found in analyses of national surveys that collect dietary and sociodemographic data from representative samples of the U.S. population. Analysis of the 1994–1996 Continuing Survey of Food Intakes by Individuals (CSFII) showed that poor Americans, defined as adults aged twenty years and older with incomes below 131 percent of the poverty threshold, tended to consume fewer servings of grains, fruits, vegetables, and dairy foods, but more servings of meats and meat alternates and more added sugars, compared with adults with higher incomes. Fewer servings of grains, fruits, vegetables, and dairy foods, and lower energy and nutrient intakes were found for men and women with less than a high-school education, a proxy measure for poverty, compared with men and women who had completed high school and beyond.

Analyses of a number of national surveys conducted between 1977 and 1996 show that dietary intakes of low-income adults have changed over time. For example, overall dietary quality improved among low-income white and Hispanic women, primarily due to reductions in total and saturated-fat and cholesterol intakes. However, fruit and vegetable intakes remained below the recommended amounts, as did those of key nutrients such as calcium, iron, and folic acid.

### **Poverty, Food Insufficiency, Food Insecurity, and Hunger**

Poverty is inextricably linked with food insufficiency (not having enough to eat some or all of the time), food insecurity (uncertainty about or inability to acquire nutritionally adequate foods in socially acceptable ways), and hunger (the physical consequence of not having enough

to eat). According to data from the Third National Health and Nutrition Examination Survey (NHANES III), food insufficiency affected 4.1 percent of U.S. households, or between 9 and 12 million individuals. Data from the September 2000 Current Population Survey Food Security Supplement showed the prevalence of food insecurity to be 10.5 percent, and the prevalence of hunger to be 3.1 percent, affecting 11 million and 3.3 million Americans, respectively. Numerous studies of national survey data have shown lower intakes of several nutrients among men, women, and children who experience food insufficiency or food insecurity. Analysis of food intakes and serum nutrients of adults from food-insufficient families has also shown lower intakes of fruits, vegetables, and dairy products, and lower concentrations of serum albumin, serum carotenoids, and serum vitamins A and E. Additional analyses of food-insufficient adults and children reveal a higher prevalence of overweight and obesity, poor health status, and iron deficiency.

Results from qualitative analyses of dietary data, in the form of ethnographic research studies, complement findings from quantitative studies and confirm differences in food choices between poor and nonpoor Americans. Poor Americans tend to consume more starches, fats, and sugars but less of foods associated with good health, like fruits and vegetables, high-fiber grains, and low-fat dairy items. Although specific food choices may differ by ethnicity or geographic location, commonalities in eating patterns exist among poor Americans. Food intakes can vary quite dramatically in the course of a month, with greater quantities and more varied foods purchased immediately after a pay period or allotment of food assistance (such as food stamps) and very limited quantities, of little variety, purchased as funds run out. Also, food intakes are not equal within households. A common occurrence is for the wife or mother of the family to reduce her intake in order to feed her children. Communal dining may also be impossible when income limits available cookware or dining facilities, or sporadic work schedules keep all members of a family from being together at one time. Feelings of deprivation, often rooted in childhood, may lead to buying nonnutritious foods (such as soda and snack foods) that are also attractive because inexpensive. Although studies show that, in theory, consuming a minimal-cost diet in accordance with the latest dietary guidelines is possible, poor Americans are more likely to purchase foods from small, nearby stores that charge an average of 10 percent more than large supermarkets farther from home.

### **Food Assistance in the United States**

Many poor Americans are eligible for federal food-assistance programs like the Food Stamp Program, the National School Lunch and School Breakfast Program, and the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC). In addition to or as a substitute for government assistance, many poor

Americans also receive charitable assistance from food pantries and soup kitchens. In 2000, 50.4 percent of Americans identified as food-insecure received assistance from one of the three federal food-assistance programs, 16.7 percent received food from a food pantry, and 2.5 percent had family members who ate at a soup kitchen. Although participation in these programs and services may reduce food insecurity, the dietary quality of participants' food may not be better than that of nonparticipants. Given societal pressures to join the dominant culture and eat the most advertised, least expensive, most accessible foods—healthful or not—the challenge is how to improve the diets of all Americans, especially the poor.

Stone Age Nutrition: The Original Human Diet  
Food Producers

#### STONE AGE NUTRITION: THE ORIGINAL HUMAN DIET

Aside from casual interest, there is a reason to appreciate the nutrition that fueled nearly all of human evolution. An increasing number of investigators believe the dietary patterns of our ancestors may constitute a guide to proper nutrition in the present. Early twenty-first-century dietary recommendations run a broad gamut, from the ultra-low-fat Pritikin program, most recently championed by Dean Ornish, to the 30:30:40 (protein:fat:carbohydrate) Zone diet of Barry Sears, to the low-carb, high-fat-and-protein Atkins diet. These popular authors are not the only ones whose recommendations vary widely, however. Academic nutritionists writing in prestigious medical journals advocate a similarly broad range of nutritional regimens, from the low-fat East Asian eating pattern to the much more fat-liberal Mediterranean approach. These conflicting recommendations, especially when they originate in respected professional publications, tend to confuse and dismay health-conscious readers who frequently learn of dietary findings through simplistic and often sensationalized media accounts. Sometimes completely contradictory nutritional findings are announced just a few years apart. For example, beta-carotene appeared to reduce cancer risk in initial studies; then it seemed to increase risk in a later investigation. Dietary fiber was first thought to reduce colon cancer susceptibility, and then it was found to have no such effect. Sodium consumption has been linked to high blood pressure in many studies but not in numerous others. High-fat diets cause coronary heart disease, but consider

the “French paradox”: the French consume at least as much saturated fat as do Americans, but they have considerably fewer heart attacks and other manifestations of coronary artery disease.

In light of such inconsistencies, it is not surprising that dietary recommendations vary. A logical, straightforward, and understandable starting point from which to develop research protocols and upon which generally accepted recommendations may ultimately be based is highly desirable. The ancestral human diet might provide such a foundation. Even though the Stone Age occurred in the very distant past, eminent paleoanthropologists, geneticists, biologists, and evolutionary theorists believe that human genes have changed hardly at all in the interim. Although many refer to modern times as the “Space Age,” genetically speaking, human beings are still Stone Agers. One can argue that the genetic determinants of our current biology were selected not for contemporary circumstances, but for the conditions of life as experienced in the remote past. There are two potential corollaries to this argument. First, that the afflictions of affluence (chronic degenerative diseases such as diabetes, many cancers, atherosclerosis [including coronary heart disease], hypertension, osteoporosis, and obesity) are prompted by dissonance between human genes and the lives of certain groups of people. Second, that the impact of these diseases, which are the major causes of illness and mortality in affluent nations, might be greatly reduced or, in some cases, eliminated altogether by reinstating essential features of the ancestral lifestyle, including relevant nutritional practices, into current existence.

Early humans, who appeared about 50,000 years ago, were hunter-gatherers (or foragers) and were similar in most respects to hunter-gatherer groups studied during the twentieth century. However, there were important differences between these groups. Modern hunter-gatherers have been increasingly restricted to infertile areas that are poorly suited to farming and where the availability of animals for hunting, especially large game, has been much reduced. Also, modern foragers generally have some contact with nearby agriculturists, which affects their culture to some extent. Hunter-gatherer groups that came under observation in the twentieth century were commonly used as models for the prehistoric and pre-agricultural peoples of 25,000 years ago. The modern hunter-gatherer groups were the best available surrogates for prehistoric peoples, but researchers also needed to consider the altered circumstances of otherwise similar people living many thousands of years apart.

### **Ancestral Foods: Plants**

The vegetable foods available to prehistoric foragers grew naturally, without cultivation, and included nuts, leafy vegetables, beans, fruits, flowers, gums, fungi, stems, and other similar items. These had been primate staples for tens of millions of years, but at some point along the ho-

minid (human-like) evolutionary track, the digging stick came into use. This simple implement widened dietary breadth by providing access to roots, bulbs, and tubers, which were plentiful but previously inaccessible sources of food energy. The nutrient values of such foods vary naturally, but if one pools the several hundred representative vegetable foods that hunter-gatherers utilized during the twentieth century and then compared their averaged nutrient content with the mean values of vegetable foods commonly consumed in Western nations, several noteworthy differences emerge. For example, wild-plant foods provide less energy per unit weight. A 3.5-ounce (100 gram) portion of the fruits and vegetables that our ancestors ate would yield, on average, only about one-third the calories that 3.5 ounces of contemporary vegetable food provide. This is primarily because so much of our current plant-food intake is derived from high-energy cereal grains—rice, corn, wheat, and the like. Stone Age humans knew that grains were a potential food source. However, given the technology available to them, the work required to process wild cereals into digestible form was generally excessive compared with the work needed to gather and process other types of wild plants. Foragers generally viewed grains as emergency goods to be used during times of shortage. It was only “late” in the human career, perhaps thirty thousand years ago in Australia and between ten and fifteen thousand years ago elsewhere (for example, the Near East), that evidence of routine cereal-grain use became common.

Another difference between the vegetable foods of the hunter-gatherers and those of Western nations is illustrated as follows. The nutrient content of wild-plant foods is high, especially when one considers the ratio of nutrients to calories. While there is, of course, considerable individual variation among these foods, a mixed grocery bag of the fruits and vegetables available to ancestral humans would provide substantially more vitamins, minerals, and fiber than would a comparably representative collection of contemporary plant foods. In many cases, vitamins and some minerals are artificially added to current foods, making them “enriched.” This enrichment process is less successful for adding fiber and is not yet feasible for phytochemicals, which are plant constituents that influence the body’s metabolic reactions. Phytochemicals can be considered semi-vitamins, but their total number (at least dozens, perhaps hundreds) is unknown and their mode of action is poorly understood. However, the importance of phytochemicals for optimal health is becoming increasingly well established. Ancestral human biology became genetically adapted to the phytochemicals provided by fruits and vegetables over hundreds to thousands of millennia. The phytochemicals of modern-day cereal grains, in contrast, are relative newcomers to the human metabolism. It is perhaps for this reason that fruit and vegetable intake appears to reduce cancer susceptibility and consumption of cereal grain products has little or no such effect.

Lastly, the plant foods available to ancestral humans afforded a fairly balanced ratio of essential polyunsaturated fatty acids. Like essential amino acids, the body does not synthesize these fatty acids—humans must obtain them from their diet. Polyunsaturated fatty acids are necessary for cell membrane fabrication, especially in the brain, and they are also the basic molecules from which eicosanoids, a large class of important locally acting hormones, are made. Essential fatty acids are divided into two families: omega 6's and omega 3's. Both types are required in mammalian physiology, but they produce opposing biochemical effects, so roughly equal amounts in the diet are desirable. Their effects on blood clotting provide a good example. If there is too much omega 6 in a person's system, their blood clots too easily, which increases the likelihood of coronary thrombosis (heart attack). An overabundance of omega 3 in a person's system reduces blood clotting excessively and increases the risk of cerebral hemorrhage (one kind of stroke). Roughly equal dietary intake of each type of these polyunsaturated fatty acids avoids both undesirable consequences. Unfortunately, in recent decades the use of safflower, corn, sunflower, and cottonseed for spreads and cooking oils has distorted the ratio. These materials contain fifty to one hundred times more omega 6 than omega 3 and, overall, Americans now consume ten to fifteen times more omega 6's than omega 3's.

### **Ancestral Foods: Animals**

The wild game that human ancestors ate differed in important ways from the commercial meats available in the twenty-first century. In the first place, modern commercial meat is fatter. Whether one compares the whole carcass or the most popular cuts (for example, flank, loin, shank, etc.), commercial meat has up to four times more fat than game. For example, 3.5 ounces of regular hamburger provides 268 kilocalories, whereas the same amount of venison yields 126 kilocalories. Even when all visible fat is removed from a T-bone steak, the resulting separable lean portion contains 30 percent more energy than game. These energy differences reflect the greater fat content of commercial meat.

Not only is there more total fat in commercial meat, but the chemical composition of the fat in this meat also varies from that in game animals. In general, fat from commercial meat has a higher proportion of saturated fatty acids (the kind that tend to raise serum cholesterol levels) than does the fat from game. Saturated fatty acids containing either fourteen or sixteen carbon atoms have a special propensity for raising serum cholesterol. Game fat typically has less than one-fifth the content of these substances when compared to an equal amount of fat from commercial meat. Another chemical difference between these two types of meat involves the essential polyunsaturated fatty acids discussed earlier. These fats are present in nearly equal amounts in wild-animal adipose tissue, as compared to the uneven ratios in most

commercial meat. Grain feeding appears to be responsible for this difference: the essential fatty acid composition of animals whose feed is based on corn becomes skewed, as their systems contain a far greater amount of omega 6 than omega 3 fatty acids.

### **Other Considerations**

Several categories of foods that are regularly consumed at present were uncommonly used or wholly unavailable for ancestral humans. These "new" foods confer some advantages, but, in several cases, there are important negatives as well.

**Grains.** Today cereal grains are "superfoods." This term is not a characterization of their nutrient properties, but rather it is recognition that in many parts of the world, members of the grain family may provide from one-third to two-thirds or more of the population's daily caloric intake. The consumption of rice in the Far East, corn in Mesoamerica, and sorghum in parts of central Africa are examples. Such a dependence on one or a few plant foods contrasts with the more broad-spectrum subsistence pattern of hunter-gatherers, who commonly utilize one hundred or more types of food plants during the year. With limited exceptions, which probably did not apply in the remote past, no one of these approaches the "superfood" status accorded cereals today.

It was mentioned earlier that ancestral humans used grains infrequently. Hand milling grains to render them digestible was such hard work that it was not desirable to use grains unless other foods were in short supply. The situation changed when pre-agricultural populations reached a point where a nomadic life was no longer feasible. This shift came about when several groups of people started to migrate towards the same areas. When people were required to settle more or less permanently in a given area, grain consumption became a viable option because other types of plant and animal food became increasingly difficult to obtain. It became apparent shortly that raising grains like wheat or barley could increase the total food energy available from a given geographical area. When people began to farm regularly, population growth accelerated to rates greatly exceeding those before the advent of agriculture. On the other hand, individual health seems to have deteriorated. People became shorter in stature, and skeletal evidence of nutritional stress and infection became more frequent. Average life expectancy also appears to have declined, so the adoption of agriculture may not have been the societal boon it is often considered. In fact, Pulitzer Prize winner Jared Diamond has called it "the worst mistake in the history of the human race" (*Discover* [May 1987]: 64–66).

**Dairy foods.** For most humans, dairy foods are important constituents of each day's diet, but for free-range non-human mammals, a mother's milk is the only "dairy product" ever consumed. After weaning, milk was not

available for any primates, including humans, until the domestication of cows, goats, camels, and the like. However, dairy foods have been an important component of official nutritional recommendations, at least in Western nations, since the first of these foods were introduced. Nevertheless, human ancestors, including behaviorally modern humans during four-fifths of their existence, thrived and evolved without any dairy foods whatsoever after they ceased breast-feeding.

**Alcohol.** In the United States, alcohol provides from 3 to 5 percent of the average adult's daily caloric intake. It is not clear when the production of alcoholic beverages first developed, but most anthropologists doubt that wine, beer, mead, and especially distilled spirits were manufactured before agriculture. No hunter-gatherer groups studied in the twentieth century made such drinks.

**Separated fats.** The fats that ancestral human consumed were generally obtained as integral components of whole foods; both animal and vegetable fats came part and parcel with the other nutrients intrinsic to the original source. In contrast, separated fats are staples for contemporary humans. Olive oil, butter, margarine, vegetable oils, lard, and the like are all vital ingredients for today's cooks. Such separated fats enhance our cuisine, but because fat provides about nine calories per gram (versus about 4 calories per gram for protein and carbohydrate), the availability of fat in this form makes it possible to increase the energy density of our food in ways our ancestors could not.

**Refined flour and sugar.** Like separated fats, refined flours and sugars allow us to create foods with unnaturally high energy density. Essentially, they are nearly pure energy—empty calories with few or no associated vitamins, minerals, or fiber. Although there are essential amino acids and essential fatty acids (required building blocks our bodies need to make necessary structural elements and required hormones), there are no essential simple carbohydrates like those available from refined flour and sugar. Such carbohydrates are a convenient and efficient source of energy, but they provide little if any nutritional benefit over and above their caloric content. Fortified flours have additional nutrients that food manufacturers consider desirable. Our ancestors obtained their carbohydrate together with the nutrients that nature provided.

**Processed and prepared foods.** Humans are the only free-living creatures that consume foods whose natural origins are obscure. Individuals unfamiliar with our culture would be unable to identify the ultimate sources of bread, pasta, sausage, cheese, and similar items that have been staples for millennia. Less traditional artificially fabricated foods became immensely popular during the twentieth century, to the point that for some people these foods, often laced with gratuitous sodium, fat, and sugar, made up most of their daily intake. The list of ingredi-

ents on the wrapper of almost any prepared-food package provides one of the most telling commentaries on the differences between contemporary nutrition and that of pre-agricultural human ancestors.

**Artificial constituents.** Organic food proponents would quickly point out that there are still other important differences between the naturally occurring plants and animals of twenty thousand years ago and most of those available to today's grocery shopper. Pesticides, hormones, fertilizers, antibiotics, dyes, and other additives are widely used in contemporary food production but were not, of course, considerations in the remote past when humans ate exclusively "organic" food. The pros and cons of these modern innovations are debatable, but there is no question that such innovations are "unnatural," and that humans evolved for millions of years before encountering the adulterated foods that most of us eat at present.

### Overall Dietary Patterns

There was no one universal pre-agricultural diet. Our ancestors ate foods that were available locally and focused on those that returned the most food energy for the least expenditure of physical energy—a general rule for all biological organisms. Two important factors affecting diet choices were latitude and rainfall. In the savanna-like environment of northeast Africa, which according to the "out of Africa" theory is thought to have been the epicenter of human evolution, both game and vegetable foods were plentiful. Gathering plant foods in such an environment was an integral aspect of the food quest for both males and females before human ancestors and those of chimpanzees diverged and for an uncertain length of time thereafter. At some point, most likely during the later stages of Australopithecine evolution, scavenging is thought to have become a significant component of hominid subsistence. It is not known whether this was an exclusively male function or whether females participated as well. Because potential competitors for animal remains included hyenas and similarly dangerous beasts, as well as the original predators, scavenging was a little less hazardous than hunting, the main difference being the degree of technological expertise required. Later, most likely for the past 500,000 years and almost certainly since the appearance of behaviorally modern humans about fifty thousand years ago, obtaining food probably resembled the pattern observed among modern foragers: a division of labor according to gender, with men hunting and women gathering.

Where large animals such as mammoths, red deer (similar to elk), horses, megamarsupials (some as large as rhinoceroses), and eland were relatively abundant, hunting them made sense in terms of energy expended. More food energy could be obtained from one such carcass than from many smaller animals, and the physical energy expended by the hunters in such a process is substantially less compared to hunting small animals. Where large

animals had become scarce, a variety of sophisticated techniques, including trapping and net hunting, were used to increase the efficiency of obtaining small game. Weirs and nets were used along rivers where fish migrated seasonally (for example, salmon runs). Stone Agers sometimes lived year-round in such locations, abandoning a nomadic life, establishing relatively large communities, and developing an early form of social stratification with elites—as opposed to nomadic hunter-gatherers who were almost always egalitarian.

Gathering was not confined to plant foods: women often brought home shellfish, eggs, small mammals, frogs, turtles, and the like. This process could be physically demanding. Women occasionally walked several miles, dug through hard ground (with a digging stick) to obtain roots or tubers, then walked back to camp carrying twenty to thirty pounds of foodstuff.

The relative contributions of hunting and gathering to a forager economy have been the subject of debate. The respective importance of these tasks almost certainly varied according to season and was surely affected by latitude. In the mammoth steppe of central Siberia, which was surprisingly well populated during the late Paleolithic era of ten to thirty thousand years ago, abundant wild grasses supported great herds of large game, especially mammoths, so hunting flourished. However, edible plant food for humans was scarce. In this region, hunting must have greatly exceeded gathering as a means of acquiring subsistence.

On the other hand, in northeast Africa, both game animals and wild plant foods were plentiful, and in such areas hunting and gathering were of almost equal importance. Early studies of foraging groups inhabiting regions of this sort suggested that about two-thirds of food was obtained by gathering. However, later analyses suggested that hunting actually made a somewhat greater contribution than gathering. The newer interpretation fit well with “optimal foraging theory,” an anthropological law that formalizes the common-sense observation that humans, like all other biological organisms, arrange their subsistence activities to maximize return relative to effort expended. When animals are plentiful and hunting techniques are well developed, as seems to have been the case for the past 100,000 years (and probably longer), the average returns from hunting exceed those from gathering. Nevertheless, gathering remained very important because even skillful hunters can experience unsuccessful periods of a sometimes of uncomfortable duration. The practical botanical knowledge of foragers is so great that the women’s success rate in finding plant food in fruitful regions approached 100 percent; many times tsi-tsi beans, baobab fruit, water lily roots, and the like would have been our ancestors’ only menu choices for dinner.

### Macronutrient Ratios

Overall subsistence patterns in East Africa are of particular interest. If the “out of Africa” theory is correct, which

seems increasingly likely, what was eaten routinely in this region affected genetic adaptation in the direct ancestors of all living humans, while what was consumed elsewhere, even as late as fifty or sixty thousand years ago, had little or no direct bearing on the contemporary human gene pool. The reconstructed nutritional patterns in this area, beginning perhaps 200,000 years ago, are quite useful to those interested in the original “natural” human diet.

With behavioral modernity came increasingly rapid cultural change, which has, to an ever-greater extent, outpaced genetic evolutionary adaptation. Because of this cultural change, subsequent dietary innovations, including the routine use of grains by everyone and of dairy foods by adults, as well as the Mediterranean, East Asian, and vegetarian approaches to healthy eating have emerged. However, these trends have appeared too recently to have had a marked effect on our genetic makeup. If there is a basic nutritional pattern to which humans are genetically adapted, the constituents provided by foods consumed in East Africa 100,000 years ago arguably define its nature.

During that time, energy intake would have been higher than at present—probably about three thousand kilocalories per day for males and perhaps 2,750 kilocalories for females. Because humans at that time lacked motorized equipment, draft animals, and the most simple machines, caloric expenditure at this level was obligatory. In fact, it is likely that up until the early twentieth century energy expenditure and intake requirements remained substantially above those typical at present.

About 55 percent of nutrients would have come from animal and fish sources, while about 45 percent, on average, would have been of vegetable origin. Total caloric intake was likely partitioned about 25–30 percent from protein, 30–35 percent from carbohydrates, and 40–45 percent from fat. These estimates differ from the contemporary American pattern and also from current orthodox recommendations:

#### Prehistoric societies

	East African hunter-gatherers*	Contemporary U.S.A.	Current recommendations
Protein	25-30%	15%	15%
Carbohydrate	30-35%	48%	55%
Fat	40-45%	34%	30%
Alcohol	—	3%	—

\* Surrogates for our earliest truly human ancestors

The differences are striking and, at first glance, suggest that the Paleolithic diet was unhealthy. A little further analysis, however, is comforting for health-conscious paleoenthusiasts.

## Fats

Our ancestors ate more fat than modern humans. Muscle meat from game animals is very lean, but Stone Agers ate everything edible, such as marrow, brain, organ meat, and fat deposits from the thoracic and abdominal cavities, not just muscle as we tend to consume today. Optimal foraging means using the whole carcass. Many different parts of farm animals, such as tripe, chitlins, tongue, sweetbreads, brain, gizzard, etc., were considered standard fare only a few generations ago, and in a few places they still are. However, in contrast to fat from today's cattle, sheep, and pigs, the carcass fat of wild animals has relatively little serum cholesterol-raising effect. Most game fat is of the cholesterol-neutral monounsaturated variety, a substantial proportion is polyunsaturated, and much less is the saturated, cholesterol-raising type. Also, ancestral foods contained little or none of the cholesterol-raising *trans* fatty acids that commercial hydrogenation adds to current diets. That the hunter-gatherer diets are heart-healthy is corroborated by the finding that the serum cholesterol levels of such people from around the world average below 130 mg/dl as opposed to a bit over 200 mg/dl for Americans. Although the available evidence is not ideal (for example, no coronary angiograms and few autopsies), coronary heart disease is virtually unknown among hunter-gatherers, as far clinical data can show. An additional factor that enhanced the heart-healthy nature of Paleolithic diets was the nearly equal proportions of omega 6 and omega 3 essential polyunsaturated fatty acids in those diets. The great preponderance of omega 6's in contemporary Western diets is believed to be a factor contributing to the cardiovascular disease epidemic in countries with such eating patterns.

## Carbohydrates

Ancestral humans ate fewer carbohydrates than is typical for contemporary humans, the major difference being the near total absence of cereal grains from pre-agricultural diets. However, the amount of fruits and vegetables consumed in areas resembling east Africa substantially exceeded amounts consumed in any part of the world and was more than double the typical fruit-and-vegetable consumption in western and northern Europe. Contemporary carbohydrates comprise refined flours and simple sugars, which are quickly absorbed and capable of inducing rapid rises in pancreatic insulin secretion. Stone Agers loved honey, but its availability was usually limited and seasonal (as indicated by their relatively cavity-free dental remains). A large proportion of ancestral carbohydrates was in the complex form that had a less adverse effect on insulin secretion.

## Protein

As far as nutritionists and exercise physiologists can ascertain, the levels of protein our ancestors consumed are not necessary for health, even for weight trainers and other high-performance athletes. On the other hand, earlier studies that attributed negative health effects to ex-

cessive dietary proteins now seem suspect. Initial reports suggested that high protein intake might cause renal failure, colon cancer, and/or elevated blood cholesterol levels. However, more recent investigations have reversed or at least significantly modified scientific opinion about their relationships. High-protein, low-carbohydrate diets have, in some cases, been shown to be beneficial. High-protein diets do aggravate kidney failure once it is established, but they do not appear to initiate the process. Autopsy studies of traditional Inuit (Eskimos) whose protein intake was extremely high did not reveal any extra incidences of kidney disease. It was once thought that high-protein diets were associated with colon cancer. There is a connection here, but this is primarily because Western diets that contain a lot of meat provide excess saturated fat along with protein, and it is the saturated fat, not the protein, which seems to foster the development of colonic neoplasms. Diets rich in meat were once thought to raise serum cholesterol levels, but here again, associated saturated fat is the culprit. High-protein diets that contain little saturated fat actually lower serum cholesterol levels, an investigative result that might have been predicted based on findings among hunter-gatherers studied during the last century.

## Micronutrients

Americans and many others in affluent nations spend enormous amounts of money on vitamins (and, to a lesser extent, minerals) presumably in the hope that consuming such micronutrients will minimize the adverse effects of an otherwise unhealthy diet and lifestyle. Nutritionists usually decry this practice, arguing that micronutrient intake above and beyond recommended daily allowance (RDA) levels is unnecessary, and that a balanced diet provides all the vitamins and minerals one needs.

From a Paleolithic perspective, there is some virtue to both these views. Nutritionists follow Stone Age practice when they argue that it is better to obtain micronutrients from real foods rather than from capsules. However, ancestral micronutrient intake exceeded RDA levels in nearly every case (sodium and, in some areas, iodine were the exceptions). The greater total caloric intake necessitated by a physically vigorous lifestyle together with a micronutrient:energy ratio much higher for ancestral foods than for those commonly consumed at present means Stone Agers typically obtained from 1.5 to 5 times the RDA levels of vitamins and minerals each day. However, they did not obtain anything near the recommendations of megavitamin enthusiasts, which can be 10 to 100 times the RDA in some instances.

Words like lycopene, anthocyanin, lutein, sulforaphane, isothiocyanate, and indole have begun to appear regularly in popular articles on nutrition. These substances and many others with equally unfamiliar names are phytochemicals, which, as noted earlier, are vitamin-like molecules that affect our metabolism and biochemistry. Phytochemicals in fruits and vegetables

seem much more vital to human health than those from cereal grains, presumably because our metabolism became adapted to the former over many millions of years as opposed to the few thousand years during which human biochemistry has routinely interacted with phytochemicals from cereals. There has been little research on the phytochemical content of uncultivated fruits and vegetables, but it is likely that the phytochemical load in such foods would have paralleled their high content of known vitamins and minerals. Based on this supposition, in addition to the fact that Stone Agers in most areas consumed abundant quantities of fresh fruits and vegetables, it is probable that ancestral phytochemical intake exceeded that of the present.

Only 10 percent of the sodium consumed in Western nations is intrinsic to the foods people eat. The remainder is added during processing, preparation, and at the table. For human ancestors, as for all other free-living terrestrial mammals, potassium intake exceeded sodium intake, a circumstance almost certainly relevant to blood-pressure regulation and to maintenance of cell-membrane electrical potential. After salt became commercially available, and especially after it became inexpensive, our diets have inverted the potassium-sodium relationship that characterized human and pre-human evolution, perhaps from the appearance of multi-cellular organisms over 500 million years ago.

## Fiber

Since Denis P. Burkitt's research first drew public attention to the value of fiber in human diets, official recommendations for fiber intake have centered on about 0.07 ounces (20 grams) per day. However, our nearest non-human primate relatives, chimpanzees, consume about 7 ounces (200 grams) of fiber per day. The fiber intake of ancestral humans would have been strongly influenced by the proportion of fruits and vegetables in their subsistence base because dietary fiber comes exclusively from plant foods. Stone Agers living at high latitudes, where edible vegetation was scarce, would have consumed even less fiber than modern humans. However, in east Africa, where modern human metabolism evolved, Paleolithic fiber intake is estimated to have been between 1.77 and 3.53 ounces (between 50 and 100 grams) per day.

There are two main fiber types, both of which are necessary for optimal human physiological function. Most plant foods provide some of each, but the proportions vary. Whole wheat and brown (unpolished) rice contain predominantly insoluble fiber, which is good for intestinal tract function. Oats, corn, and most fruits and vegetables provide a high proportion of soluble fiber, which is valuable for regulating cholesterol absorption after meals. Modern, refined grain-centered diets generally have too little fiber, but, in addition, they have a disproportionate amount of insoluble fiber. Pre-agricultural diets featuring more fruits and vegetables than at present provided a better balanced insoluble-to-soluble fiber ratio.

## Conclusion

The uncultivated plant foods and wild game that nourished ancestral humans and their pre-human predecessors were those to which our genetic makeup became adapted. Increasingly rapid cultural innovations during the past few thousand years have transformed our nutrition such that Cro-Magnons might not recognize many constituents of a typical meal. However, genetic evolution during the same period has been glacially slow; thus human beings' genetically determined biology remains adapted for the literally natural and organic foods of the remote past. This dissonance between human genes and human lives has critical implications for human health.

## FOOD PRODUCERS

The more than six billion humans living on earth at the beginning of the twenty-first century were almost exclusively dependent upon a narrow range of domesticated foods produced on some thirty-eight percent of the world's total land surface. More than three quarters of our annual global harvest is cereal-based, the bulk of which is composed of as few as four species. Although humans and their ancestors have inhabited the earth for several million years, food production is relatively recent, spanning the Holocene epoch or last ten to eleven millennia. The two thousand or more species of plants and animals that humans domesticated during this relatively brief period represent only a tiny fraction of the earth's biota, and with some recent exceptions of minor exotic or luxury foods, most of the important dietary items were domesticated relatively early on.

From the beginning of the Holocene, plants and animals have been selectively bred to provide food and

medicine, clothing and companionship, draft and transportation, tools and weapons, and fertilizer. Domestication can increase the efficiency and reliability of food procurement, which can further facilitate an increase in human population size and density. While some hunter-gatherers are highly sedentary and many farmers somewhat mobile, food production often provides the necessary foundation that enables larger populations to live in fixed settlements for longer periods of time.

## Domestication

Domestication is not a discovery but a process by which humans modify plants and animals by selectively encouraging certain characteristics that they want. In time, the domestication process can so genetically alter a population that it is no longer capable of flourishing in the wild. This dependency is usually bidirectional as humans and domesticates become reliant upon each other for survival. The process of domestication can be deliberate or unintentional as humans select for specific qualities of interest. Certain plants and animals are somewhat preadapted to domestication. Seed plants, for example, often thrive as weeds that colonize sunny clearings exposed by human occupation. Over time, subtle and important changes in the original population structure can be encouraged by inadvertently dropping or intentionally planting selected seeds in and around these open areas.

What characteristics do humans select? Domesticated plants mature simultaneously and lack the botanical ability to self disperse, attributes which are controlled by and for human consumers. Rapidly germinating plants that produce seeds with greater initial reserves and thin coats are desired. Self-pollinating plants that readily adapt to the conditions of human settlement are also favored. Preferred animals include: fast growing herbivores that can be economically raised and consumed; docile taxa that can be bred in captivity; and herding species with a natural dominance hierarchy that humans can readily commandeer. Characteristically, many of the earliest domesticated plants were locally exploited and rapidly growing self pollinators that produced high yields of readily storable edible seeds. Early domesticated animals included locally available generalists that were placid, gregarious, and amenable to confinement.

## The Geography of Early Domestication

Where and when were certain plants and animals initially domesticated? The Swiss botanist and geographer Alphonse De Candolle (1779-1841) was the first to document the geographical origins of cultivated plants, a subject that was greatly elaborated by the Russian botanist and geneticist Nikolai Vavilov (1887-1943?), who suggested that the area of origin for a domesticate was likely centered in regions where it is presently most diverse. Currently, with the aid of genetics and molecular techniques, archaeologists, biologists, and geographers attempt to delineate the area in which a plant or animal may have been first domesticated by defining the present

Independent areas of early prehistoric food production.

geographical distribution of its known wild progenitor and studying its subsequent development therein.

The early history of food production is an interdisciplinary undertaking which combines the techniques and methods of archaeology, botany, and zoology. Primary data are often recovered using specialized techniques and methods like flotation devices and pollen corers, and include preserved seeds, pollen, starch grains, phytoliths or mineral impressions of plant cell walls, bones, teeth, horns, and hair. Inferences are also drawn from tools, agricultural infrastructure, cultural implements, artistic portrayals, and written accounts. We can estimate how old our primary evidence is by radiometrically dating associated materials or the preserved organics themselves. Nevertheless, the entire endeavor hinges on the vagaries of sampling, luck of preservation, and intensive fieldwork. As a result, we understand the early origins of food production better in some areas than we do in others.

Much of the earliest evidence for food production comes from sites in arid areas. This may be simply because our primary data preserve better in these settings; however, the bulk of our major contemporary crops appear to have originated in regions with protracted dry seasons. We can identify some relatively circumscribed regions in which a core founder population of local plants and/or animals was originally domesticated. In other areas, the pattern of domestication was likely more diffuse. We can also recognize regions into which all or a few of the founder domesticates were introduced, after which local species were domesticated. Often it is difficult to

know precisely whether or not the introduction was through indigenous adoption or direct population invasion from outside. Currently, we can recognize some five to nine early areas of independent food production, from where domesticates, people and their domesticates, and/or the idea of domestication may have spread to other regions.

### West Asia

We find our earliest and so far best evidence in a 2000 km arc of southwest Asia, bounded to the north by higher forested terrain and to the south by desert. This Fertile Crescent stretches from the eastern shores of the Mediterranean north of the Negev desert, around present day Syria and Turkey, and into the plains of the Tigris and Euphrates where it is bordered in the east by the Zagros mountains of present day Iran. Here, climatic amelioration at the end of the Pleistocene created local conditions suitable for large stands of wild grasses with abundant forage for various grazing herbivores. This topographically and floristically diverse region was rich in large-seeded and self-pollinating annuals adapted to seasonal rainfall and protracted dry seasons. It also supported a diverse population of mammals which, apart from the dog (*Canis familiaris*), included the world's earliest domesticated animals.

Around 10,000 B.P. (before the present) we find evidence for domesticated barley, first as a two-rowed (*Hordeum vulgare ditichum*) and somewhat later as a six-rowed (*H. v. hexastichum*) variety, along with emmer

(*Triticum turgidum dicoccum*) and einkorn (*T. monococum*) wheats. Possibly after 9000 B.P., sheep (*Ovis aries*) and goat (*Capra hircus*) were domesticated in the north and east respectively, with the subsequent additions of domesticated pig (*Sus scrofa*) and cattle (*Bos taurus*) from present day Turkey. At roughly the same time, the early menu was supplemented with domesticated pulses, especially lentil (*Lens culinaris*), pea (*Pisum sativum*), chickpea (*Cicer arietinum*), and bitter vetch (*Vicia ervilia*), along with flax (*Linum usitatissimum*) for oil and fiber. The protein rich cereals provide an excellent source of carbohydrates but lack an essential amino acid for the manufacture of animal protein. This is provided by the pulses, which can also fix nitrogen into soils when planted alongside cereal crops. Flax was used for textiles and oil, while animals provided a reliable protein source, and were eventually used for dairying, clothing, traction, and transport. Together, this balanced package formed an important founder population of domesticates that variably spread into other world regions.

Archaeological evidence tracks the rapid diffusion of Neolithic food production to the African and European shores of the Mediterranean by 8000 B.P., and a little later into Italy, Greece, and the Balkans. Farming spread quickly throughout temperate Europe after 7000 B.P., reaching Scandinavia and England by around 5000 B.P. We also see the appearance of southwest Asian food production in the Nile Valley by 6500 B.P., and farther abroad into Ethiopia and the Indus Valley. Western domesticates reach China by 3300 B.P.

In most cases, we don't know whether these patterns represent foreign food producers who migrated into new regions, local populations that adopted farming due to external stimulus, or a mix of both. We do know that many important cultivars were subsequently domesticated. A list of some of the more popular and their possible region of origin includes: faba bean (*Vicia faba*), olive (*Olea europaea*), grape (*Vitis vinifera*), fig (*Ficus carica*), and date (*Phoenix dactylifera*) in the Near East and Fertile Crescent; bread wheat (*Triticum aestivum*), rye (*Secale*), hemp (*Cannabis sativa*), lettuce (*Lactuca sativa*), and horse (*Equus caballus*) in western Asia; dromedary camel (*Camelus dromedarius*), and coffee (*Coffea arabica*) in Arabia; Old World cotton (*Gossypium*) in the Indian subcontinent; oat (*Avena sativa*), and poppy (*Papaver somniferum*) in Europe and the Mediterranean; and, donkey (*Equus asinus*) in Egypt.

### East Asia

An early center of cereal based food production is found along the Huang Ho (Yellow) River in northern China. Transitionally located between semi-arid uplands to the west and forested plains to the east, prehistoric farmers cultivated foxtail (*Setaria italica*) and broomcorn (*Panicum miliaceum*) millet by at least 7500 B.P. Although the area was likely warmer and wetter at the time, both plants are somewhat drought resistant. Shortly thereafter, diet

was supplemented by domesticated chicken (*Gallus gallus domesticus*) and pig. Although pigs were possibly present in southern China a thousand years earlier, either claim can support an ancient introduction from western Asia or independent domestication. Some later domesticates from north China include soybean (*Glycine max*), hemp (*Cannabis*), popular tree fruits like Chinese pear (*Pyrus pyrifolia*), peach (*Prunus persica*), apricot (*P. armeniaca*), varieties of apples (*Malus domestica*), species of cherry (*Prunus* spp.), and silk worm (*Bombyx mori*), along with many local derelict cultivars that survive today as weeds.

To the south, wet rice agriculture developed by 8000 B.P. along the Chang Jiang (Yangtze) River. Early evidence comes from the middle and lower reaches of this wet and marshy region, where varieties of long-grained (*Oryza sativa* var. *indica*) and short-grained (var. *japonica*) rice may have been domesticated at a time when temperatures were warmer than today. Some two thousand years after possible pig domestication in south China, water buffalo (*Bubalus bubalus*) is recorded south of the Chang Jiang delta, along with bottle gourd (*Lagenaria siceraria*) and cultivated aquatic plants including water caltrop (*Trapa* spp.) and fox nut (*Euryale ferox*). Other notable domesticates from south China include water chestnut (*Eleocharis tuberosa*), Asian arrowroot (*Sagittaria sinensis*), red bean (*Vigna angularis*), and duck (*Anas platyrhynchos*).

Although domesticated rice is found in India and Southeast Asia as early as 5000 B.P., east Asian domesticates dispersed less quickly into Europe and western Asia. Rice was unknown to much of the West before Hellenistic times, and many domesticates were only introduced through merchant voyaging in the past five to six hundred years. It is unknown whether or to what extent the introduction of rice agriculture into Southeast Asia supplanted an indigenous domestication of root and tree crops, which included yam (*Dioscorea* spp.), bananas and plantains (*Musa* spp.), citrus (*Citrus* spp.), mango (*Mangifera indica*), breadfruit (*Artocarpus* spp.), and various spices. Tantalizing evidence hints at the possibility of early agriculture in Papua New Guinea around 9000 B.P. Many plants were domesticated in the Pacific islands, including sugarcane (*Saccharum officinarum*), coconut (*Cocos nucifera*), taros (*Alocasia*, *Cyrtosperma*, *Colocasia*), sago (*Metroxylon*), kava (*Piper methysticum*), and numerous spices. We can trace a relatively early spread of southeast Asian food production into nearby islands, beginning in Taiwan as early as 7000 B.P. and subsequently spreading to Borneo by 4500 B.P. Subsequent colonization into Polynesia between 3500 and 2500 B.P. introduced fowl, dogs, pigs, and various root and tree crops.

### Africa

Before west Asian farming arrived in the Nile Valley, the Sahara was inhabited by nomadic pastoral groups that herded indigenous domesticated cattle along with sheep or goat introduced from the Mediterranean. The south-

ern boundary of this early “pastoral neolithic” was controlled by tsetse fly infestation in the forests and savannas of sub-Saharan Africa, where nagana disease wasted domestic livestock. Early evidence for indigenous African plant domestication in savanna and Sahel regions south of the Sahara include native grains like sorghum (*Sorghum bicolor*) around 4000 B.P. in Niger, pearl millet (*Pennisetum glaucum*) after 3000 B.P. in Mauritania, and African rice (*Oryza glaberrima*) after 2000 B.P. in Mali. Other important African domesticates with possible savanna origins include cowpea (*Vigna unguiculata*) and African yams (*Dioscorea* spp.). Finger millet (*Eleusine coracana*) and tef (*Eragrostis tef*) were locally domesticated in the highlands of eastern Africa, as were ensete (*Musa ensete*), noog oil (*Guizotia abyssinica*), and narcotic chat (*Catha edulis*).

Forest zones contributed oil palm (*Elaeis guineensis*), kola nut (*Cola nitida*), and guinea fowl (*Numida meleagris*) in the west, and okra (*Hibiscus esculentus*) and robusta coffee (*Coffea canephora*) in equatorial Africa. The somewhat misnamed Arabian variety (*C. arabica*) actually originated in mountain forests of southern Ethiopia and Sudan. Desertic regions contributed cantaloup (*Cucumis melo*), watermelon (*Citrullus lanatus*) possibly after 3000 B.P. in Mauritania, and perhaps date (*Phoenix dactylifera*). The house cat (*Felis catus*) may have been domesticated in Egypt, where we also see early evidence for bottle gourd around 5500 B.P. Archaeologists have traced the later diffusion of pastoral groups into southern Africa as they reached the Cape coast by the time of Christ.

## North America

Early evidence for a nutritionally balanced founder population of domesticated squash, beans, and maize is found in Mesoamerica. Orange pumpkin squashes (*Cucurbita pepo*), that today include acorn and zucchini varieties, appear around 10,000 B.P. in Mexico. Ancient farmers may have selected squash for their seeds rather than pulp, later adding winter (*C. moschata*), cushaw (*C. argyrosperma*), and fig leaf cultivars (*C. ficifolia*). The chayote (*Sechium edule*) was more recently added, while ancient evidence for the bottle gourd suggests that it may have rafted across the Atlantic from Africa. The common bean (*Phaseolus vulgaris*) was independently domesticated twice, once in Mexico as early as 6000 B.P., and later joined by members of the same genus including tepary (*P. acutifolius*), runner bean (*P. coccineus*), and botil (*P. polyanthus*). Maize (*Zea mays*) was likely domesticated from a wild teosinte in southwestern Mexico. Direct dating of maize remains suggests its earliest appearance around 5500 B.P., after which it spread rapidly throughout the hemisphere. The common chile pepper (*Capsicum annum*) is also found very early in Mesoamerica. Later domesticates of note include grain amaranths (*Amaranthus* spp.), tomatillo (*Physalis philadelphica*), tree crops like cacao (*Theobroma cacao*) and sapote (*Pouteria sapota*), hairy cotton (*Gossypium hirsutum*), various species of Agave for hennequen and sisal fiber, as well as fermented drink, and a domesticated bird, the turkey (*Meleagris gallopavo*).

Maize appears in the American Southwest by 3500 B.P., but becomes a major staple with squash and beans much later. By 2000 B.P. maize eventually enters the southeast, where independently domesticated squash (*Cucurbita pepo*), sunflower (*Helianthus annuus*), marsh elder (*Iva annua macrocarpa*), and goosefoot (*Chenopodium berlandieri*) were all already under cultivation, possibly by 4500 B.P. Some 2000 years later, erect knotweed (*Polygonum erectum*), maygrass (*Phalaris caroliniana*), and little barley (*Hordeum pusillum*) assume greater dietary significance, but only after roughly 1000 B.P. does maize-centered agriculture dominate eastern North America.

## South America

An early complex of domesticates that may have developed by 5000 B.P. in highland areas from south-central Peru to Bolivia, eventually dispersed throughout the ancient Andean world by the time conquering Spaniards arrived. Included were quinoa (*Chenopodium quinoa*), kaniwa (*C. pallidicaule*), and kiwicha (*Amaranthus caudatus*), all high altitude pseudocereals that provide flour for baking, soups, and beverages. Indigenous tuber crops like oca (*Oxalis tuberosa*), mashua (*Tropaeolum tuberosum*), ullucu (*Ullucus tuberosus*), and potato (*Solanum tuberosum*) are also adapted to the cold conditions of high elevation.

The only native New World mammalian domesticates, llama (*Lama glama*), alpaca (*L. pacos*), and cuy or guinea pig (*Cavia aparea porcellus*) round out the highland package. Direct dating of archaeological specimens indicates that domesticated South American common (*Phaseolus vulgaris*) and lima (*P. lunatus*) beans were added somewhat later, possibly at slightly lower elevations in the southern highlands. Other Andean domesticates included roots like maca (*Lepidium meyenii*), and arracacha (*Arracacia xanthorrhiza*), and tree crops as pepino (*Solanum muricatum*) and tree tomato (*Cyphomandra betacea*).

Phytolith evidence could suggest the appearance of maize around 7000 B.P. in northern neotropical lowlands; however, others argue a more recent introduction around 4000 B.P. in accordance with Mesoamerican data. Early lowland contexts also reveal domesticated jack beans (*Canavalia plagioperma*), cotton (*Gossypium barbadense*), and the root crops achira (*Canna edulis*), leren (*Calathea allouia*), and arrowroot (*Maranta arundinacea*). Phytolith evidence also supports early use of bottle gourd and squash; indigenous domesticated squash include the hubbard (*Cucurbita maxima*) originally from Argentina, and possibly the relict *C. ecuadorensis* of southwestern Ecuador. Many domesticates come from areas of the lowland neotropics, including: manioc (*Manihot esculenta*), cocoyam (*Xanthosoma* spp.), yam (*Dioscorea trifida*), sweet potato (*Ipomoea batata*), peanuts (*Arachis hypogaea*), capsicum peppers (*Capsicum* spp.), various drug and medicinal plants, tree and palm crops like cashew (*Anacardium occidentale*), avocado (*Persea americana*), guava (*Psidium guajava*), and peach palm (*Bactris gasipaes*), and the muscovy duck (*Cairina moschata*).

## Why Domesticate?

Ancient agriculturalists customarily attributed their origins to an act of divine intervention. As scientists began to seek alternative explanations for the beginnings of food production, they persisted in the teleological assumption that domestication was initially a discovery. Cultural innovation took place especially in areas where resources were concentrated, either naturally or as unintended consequence of human behavior. It is, however, reasonable to assume that humans everywhere possessed, from earliest times, a sophisticated understanding of the plants and animals that surrounded them. This is easily confirmed in the detailed knowledge of hunter-gatherers who, moreover, actually spend less time procuring food than their agricultural brethren. Bioarchaeological study of skeletal assemblages also indicates that early agriculturalists may have suffered poorer health than hunter-gatherers. So, why bother to produce food? Causation came to be viewed as a response to stress or disequilibrium; humans began to produce food in order to keep up with unceasing population growth and/or as an adaptation to their changing environment. Some view the adoption of food production as the product of rational economic decisions in which optimizing foragers weighed costs against benefit. Others seek social origins for early agricultural, suggesting that early cultigens were originally prestige items used in specific, highly politicized contexts.

Whatever the ultimate cause, it appears that food production antedated the appearance of sedentary village life. It likely took place in settings where populations were neither internally nor externally threatened, and evolved out of a lengthy mutualistic association between plants, animals, and humans. The distinction between domesticator and domesticated is simply a matter of perspective, as food and food producers eventually launched a trajectory that would irreversibly change the way we live.

**PREPARATION OF FOOD.** Food preparation has been a constant chore since the first human beings picked up cutting and mashing stones. In return, this effort to make food edible, preserve it, and transform its character has sustained an ever-increasing population. Many techniques, including grinding, sifting, drying, salting, sealing, fermenting, and applying heat, are extremely ancient. Few fundamentally new techniques have been introduced in the past two centuries, among them microwaving. The main long-term change has been the shifting of tasks from the domestic hearth to centralized factories.

The processes of food preparation might be divided according to their primary science, whether physical (such as extracting nuts from their shells), chemical (adding salt), or biological (brewing beer). Perhaps more helpfully, they might be categorized according to their intended purpose. Some foods are toxic until prepared properly. Others are scarcely edible until softened. Preparation can bring together nutritional variety. It can add intriguing flavors. Food preparation can also have negative impacts, especially on nutrients.

Viewed socially, food preparation has typically been female work, requiring hours of often hard and repetitive effort. Over history, it has gradually been shifted out of the home and typically made a male concern. Butchery, milling, baking, and brewing are among the oldest extradomestic industries, conducted by specialists for thousands of years. These and most other tasks have been more scientifically and centrally managed over the past two centuries.

Preparation is a core human activity that can be examined from the perspectives of many biochemical, nutritional, technical, cultural, social, historical, and economic sciences. Many aspects of food preparation are treated in greater detail elsewhere in this work. This entry outlines its purposes, its history and social position, and provides snapshots of people at work, from an an-

Large-scale food preparation requires large-scale solutions. In the traditional culture of Cyprus, entire villages are invited to wedding feasts, which necessitates moveable ovens, since all of the food is baked in earthenware pots. The blending of tradition and modern technology is evident in this catering invention, which will feed about six thousand people. PHOTO ILYA LOYSHA.

cient Roman peasant making a *moretum* (suggestive of an Italian pesto) to global corporations preparing hamburgers.

### Defining “Preparation”

In *Cooking, Cuisine, and Class*, social anthropologist Jack Goody distinguishes five basic phases in the process of “providing and transforming food”: namely, production (growing on the farm), distribution (market activities, including storage), preparation (cooking in the kitchen), consumption (eating at the table), and disposal (clearing up) (p. 37). While such a production chain might seem straightforward, it can be misleading. Traditionally at least, food preparation included preservation and storage. Preparation thus came immediately after food “production” in the sense of hunting, gardening, and farming.

It is even harder to define where preparation ends, giving way to such possible next steps as “consumption,” “cooking,” “serving,” or “eating.” Just the word “consumption” has two basic meanings. It can be eating, in which case preparation includes the fullest possible range of food handling. Consumption can also mean purchasing in the modern market, which possibly leaves some

cooking to be done in the domestic kitchen. “Cooking” introduces further complications, because this can mean the transformation of food with heat (the usual dictionary definition) or something more all-encompassing.

These definitional problems arise because food preparation is viewed as a transformation of a plant or animal into food to the neglect of some basic social considerations, in particular, distribution. Central institutions, markets, and meals can distribute food at any point between “raw” and “cooked.” For example, the breaking down of an animal carcass into small cuts of meat almost seems to come before “preparation” (because the nutritional change is marginal), but its social implications are crucial, for the best serves have typically gone to the most powerful people. Restaurants distribute food not even as semiprepared products but as finished meals. Accordingly, restaurant preparation (often called just “the prep”) is done before the customer arrives—the food is taken from its packages, neatly chopped, and perhaps partly cooked. When the cooks turn their attention to “service,” they concentrate on last-minute stove work and assembly, which might be translated as “serving out in the kitchen.”

The appearance of “preparation” thus largely depends on which stage of its distribution the food is being prepared for. For the purposes of this discussion, “preparation” comes early in the raw-cooked continuum. It is closer to the farm, whereas cooking is found nearer the table. Preparation’s transformations are oriented toward nutrition and palatability rather than more purely social and cultural aspects, such as presentation and serving.

### Basic Techniques

Food preparation techniques range from chopping up through fermentation and emulsifying to pressure-cooking, vacuum packing, and homogenizing. One way to understand them is to examine immediate purposes, which can be categorized as separating out edible foods; removing toxins; softening and otherwise making ingredients more edible and digestible; distributing foods; storing them; and making them into new compositions.

**Separation.** The immediate need for preparing food is the separation of edible from inedible parts. This includes simple shelling, peeling, husking, and sifting. Sometimes such hazards as small stones need removing. The separation of cream may involve machinery, but the tools and techniques are generally not complicated. Some steps in meat butchery come under this heading.

**Detoxification.** Some foods have to be made safe to eat. Among important examples is the root, cassava, which forms prussic acid that can be dispelled by soaking and cooking. The green color appearing near the skin of potatoes is simply cut off. Expert cutting is also required with the notorious Japanese delicacy, the *fugu* or puffer fish. Communities have traditionally been amazingly adept at dealing with local dangers, because learning to recognize and treat hazardous species must have necessitated long, life-threatening trial and error.

**Making edible and digestible.** The next major purpose of preparation is making food more easily chewed and digested. This can be achieved by a range of techniques, such as grinding, pounding, soaking, and cooking in the sense of heating, which includes boiling, roasting, baking, steaming, shallow and deep frying, and microwaving.

In the case of wheat, for example, the heads of grain must be threshed to break them up, then winnowed to separate the wheat from the chaff. After that, it is probably ground into flour, which can again be separated and perhaps soaked or turned into a paste. The flour mixture can then be poured on a plate and fried, shaped into a loaf to be fried, baked or roasted, or pulled, extruded, or rolled out as noodles or pasta, when it is commonly boiled.

**Distribution.** Food is transported in the arms, bark containers, pots on the head, baskets, panniers on donkeys, ships, trains, and refrigerated trucks, all of which involve various kinds of preparation. Food is also physically divided up, especially with the use of knives and

cleavers, and the central social role of knives is outlined by Michael Symons in an essay in historical sociology called “Cutting Up Cultures.”

The butchery of meat can be viewed as distribution; for example, everything is used of a pig “but the squeal.” A small festival occurs during the division of a household pig into numerous parts, washing the intestines for sausage casings, preserving legs with salting and drying as ham, making pancakes from the blood, and so on. Commercial pig distribution is known in France as *charcuterie*.

**Storage.** Some foods such as grains and roots are more readily storable without preparation. They might just need to be kept in a cool, dry, airy place or left buried, and protected from pests. Others can be prepared to greatly extend their storage life. Preservation methods include drying, salting, pickling, sealing, cooking (heating), smoking, candying, fermenting, and freezing. These mainly rely on making a hostile environment for microorganisms that produce decay. For example, sealing keeps air away by placing the food perhaps under oil, in a tight container or under a vacuum. Through the changes introduced by fermentation, milk can be kept as cheese, soybeans turned into soy sauce, grain and fruit made into beer and wine.

**Composition.** Some preparation techniques amalgamate more than one ingredient into a composition: what might aptly be called a new preparation. A variety of foods might be simmered together to make the family of sauces, stews, and soups. The use of yeasts in dough makes breads rise. A sophisticated technique is emulsification (effectively, the mixing of oil in water), which is employed to make a range of sauces, such as hollandaise.

### History

In social terms, food preparation has largely been done by women. Among the numerous tasks, women have carried the water. They have tended the fire, fetched firewood, and found a light. They have ground and pounded with stones. Spanish gastronomic author Alicia Ríos spoke of the mortar and pestle as an everyday contrivance at the Oxford Symposium on Food and Cookery in 1988. She extolled the “rhythmic drumming of pestles pounding in mortars, coming from the kitchens of city tower blocks and quiet village houses. The familiar sound is the hint of aromas to come.” The pestle originally made grains edible, its crushing action replicating the human jawbone. As a second main task, “a variety of sometimes opposing elements are mixed together,” achieving an “integration.” For Ríos, “the use of the mortar is universal,” although she accepted that a “question mark hangs over the continued survival of this instrument which is at the same time practical, magical and symbolical.”

If the first social generalization is that food preparation has largely been done by women, then the second is that this labor has through history been taken over by

industry, shifting the work to the public, male-controlled sphere. That is, the homely pounding and “integration” that Rios found all around her have, for many others, disappeared behind factory walls.

The basic methods of food preparation are extremely ancient. Some techniques, such as podding and peeling, are shared with other animals. The use of tools suggests distinctively human behavior, the pestles augmenting the jawbones and various cutting implements extending the claws and teeth. The earliest social groups are thought to have been essentially opportunistic omnivores, who could scavenge in a range of habitats. Food preparation further increased the available species through detoxifying and softening, in which fire eventually played a crucial role.

When people adopted the settled, agrarian way of life around 10,000 years ago, they constructed shelters for food that became shelters for themselves as well, for the secret of the agrarian mode of production was food storage. Initially, this meant collecting and then growing basic foods, such as seeds, roots, and tubers that had intrinsic keeping qualities. Early settled societies also kept otherwise perishable foods through drying, sealing under oil, fermenting to make cheese, and so on. The keeping qualities of foods often make them less humanly digestible, too. Accordingly, the settled, food-stockpiling way of life required a range of basic preparation techniques to “pre-chew” and “pre-digest.”

The settled mode was also marked by increased division of food preparation among specialists. Men had long hunted, cut up, and roasted meat, leading some anthropologists to characterize roasting as “male” as opposed to “female” boiling. Other tasks then went to artisans, including millers (using human, animal, water, and wind power and eventually engines), bakers, and brewers. Most of these were male tasks, although taverns were often run by women.

Pre-industrial food preparation was often done within close domestic groups, villages, temples, and palaces. But this compactness of production, distribution, preparation, and consumption broke down. Salt was among the earliest traded commodities. Spices were light and considered desirable enough to carry over vast distances. Such trade might have originally been between chiefs and kings, but markets opened up, and an increasing range of prepared foods exchanged.

As an illustration of women’s domestic manufacture for medieval markets, Swedish rural historian Janken Myrdal has described the spread of the plunge churn for butter making. Butter fat had long been separated by shaking milk in a skin, pot, or wooden vessel. By about 1,000 years ago, the plunge churn had taken over across a wide area of Europe and Asia. Myrdal found much the same plunge churn, a cylinder usually of wood and up to about 3.3 feet high, from Ireland to Tibet. The plunging of the milk of cream with a staff above a cross or disk

causes the fat to coagulate. Since the plunge churn requires a relatively large amount of liquid, Myrdal suggests that its introduction must have accompanied a widespread stimulus to commercial production. At least in Europe, this probably came from the entrenched feudal social structure, with tenants having to pay rents and taxes, which they did in a luxury food, butter.

The trade routes eventually brought the so-called New and Old Worlds together. Ocean voyages depended on salted and pickled foods, along with ship’s biscuits. These became some of the earliest industrial food products. Bottling or canning was developed by Nicolas Appert in France at the close of the eighteenth century, aimed initially at seafarers, the armed forces, and other mobile populations.

The effects of refrigeration have long been applied through the use of cool, dry spaces. In China, ice was employed in transport at least by the seventeenth century, because Frederick W. Mote observes in *Food in Chinese Culture*, edited by K. C. Chang, that “refrigerated shipping also seems to have been taken for granted in Ming times, long before we hear of such a development in Europe” (p. 215). During the nineteenth century, ice was carried across oceans from New England lakes, and railway networks adopted ice for food transport. In 1850 an Australian, James Harrison, designed the first practical ice-making machine.

“Roller” flour mills were used from the 1870s, quicker and easier than grinding between flat stones, as well as producing whiter flour. Breakfast cereals were developed in United States to meet needs of vegetarian groups, notably Seventh Day Adventists. From that time, artisanal businesses that had grown into regional ones became national and finally global corporations. Capital had been invested first in agriculture and from the mid-nineteenth century in food preservation and distribution. The third major step reorganized the final cooking of food in the second half of the twentieth century.

### Food Quality

The need to supply the rapidly expanding cities of the early nineteenth century made more room for food adulteration. Various writers sought to draw public attention to this practice, Frederick Accum causing the greatest stir with a *Treatise on the Adulterations of Food and Culinary Poisons* in 1820. The considerable work then done by Dr. Hassall and others to improve the honesty of food preparation in the 1850s is also described by Jack Drummond and Anne Wilbraham in the *Englishman’s Food*.

The rush to industrialize food preparation could not be stopped, however. Writing under the initials “M. M.” in 1851, Mary Allen Meredith complained in her article “Gastronomy and Civilisation” in *Fraser’s Magazine* (no. 264) that “[w]e have let the beer of the people disappear, and have grown ashamed of roast beef. . . . Draught ale has vanished, and all the bottled compounds that go by

that name are but unwholesome concoctions of drugs and camomile. We have brought chemistry into our kitchens, not as a handmaid but as a poisoner.”

Nineteenth-century gourmets sometimes hailed bottled fruits out of season, and believed that some mass-prepared items such as packet spaghetti (or *pastasciutta*) could maintain high quality; other oddities such as jellies and sweet corn in cans gained nostalgic appeal. However, these were exceptions, and in the early twenty-first century the balance of gastronomic opinion is against factory preparation. The food processing industries that so effectively supplied armies and, increasingly, urban populations generally degraded quality. The main trouble seems to be the drive to reduce costs. Highly processed foods are then brought back to life, so to speak, through cosmetic means, supplemented by vivacious marketing.

A writer specializing in Jewish cooking, Evelyn Rose, told the Oxford Symposium of Food and Cookery in 1987 about her experiences in recreating “homemade” flavor for a commercial supplier of kosher products, Rakusen’s Ltd., in Leeds, England. She worked with the firm on canned soups since they presented relatively minor processing challenges. Any use of additives put canned soups “into a different category” from homemade ones, she found. For example, “modified starch” thickeners gave a glutinous texture and diluted flavor, and flavor enhancers left a synthetic taste. Accordingly, to thicken Rose’s Tuscan bean soup, they puréed half the solids. To stop her Dutch pea soup from becoming the color of “mud,” they used new technology and top quality split peas. To ensure chunks of vegetables were neither so large as to be unsightly nor so small as to melt away, she specified precise dimensions. While the homemade flavor was “universally acknowledged,” she reported that the soups had to be sold at the same “luxury” price of game soup and lobster soup.

With the transfer of food preparation from households and local artisans to commercial factories, using increasingly complex processes, the ordinary person lost skills and knowledge. This was accompanied by an enormous inrush of information of other kinds. On one hand, this was dietary, with increasingly obese and otherwise unhealthy populations concerned about the quantity of fat and sugar, especially in so-called junk foods. On the other hand, the lack of real knowledge was replaced by commercial image making.

The resulting consumer confusion can be illustrated by the scandal when Snow Brand milk poisoned more than 16,000 people in Japan in the summer of 2000. The cause was publicly revealed to be contaminated nonfat dry milk (NFDm). This drew widespread attention to the fact that much “milk” was not raw (fresh) milk but powdered milk, which gave manufacturers much more flexibility in their operations, bulking out supplies in the off-season and adjusting the chemical balance of special milks. Ironically, the contaminated NFDm in Japan went into just those types of milk preferred by “health con-

Food is often prepared at the table, as in the case of this curious old implement called Passmore’s Patent Conjurer made by Thomas Passmore of Philadelphia, circa 1797. Constructed of sheet iron and wrought iron, the conjurer permitted small articles of food such as oysters or lamb chops to be cooked over oil lamps in the manner of a pressure cooker. ROUGHWOOD COLLECTION. PHOTO CHEW & COMPANY.

scious” people who had been persuaded to purchase calcium-enriched, lowfat milk and yogurt drinks.

### An Early Account of Food Preparation

The Latin poem *Moretum* is perhaps the oldest surviving detailed account of a person preparing food. Scholars used to think it was written by Virgil, but now credit an unknown successor between 8 and 25 B.C.E. The poem, which has been translated and introduced by classicist E. J. Kenney, describes the preparation of a basic meal in order to convey the hand-to-mouth grind of peasant life.

On a winter’s morning, while still dark, the rustic cultivator, Simulus, gropes for the hearth and eventually coaxes the embers into fire. He fetches some grain from a “miserable heap” in a cupboard. His right hand turns the grinding stone rapidly, with the left feeding it, until he reverses arms from weariness. Singing an uncouth country song, he sieves the meal, the black siftings staying on the upper surface, the unmixed flour sinking through the holes. He piles it on a smooth board, pours on water warmed by the flame, and works the mixture until it becomes cohesive, occasionally sprinkling with salt. He smooths the kneaded dough into regular rounds, marking each with the characteristic eight segments of a Roman loaf. He inserts it into a swept part of the hearth,

covers it with crocks (pieces of broken pottery), and heaps fire on top.

So that bread alone should not displease his palate, Simulus finds an accompaniment. He has only a round cheese pierced through the middle with a string. So our “far-seeing hero” contrives another resource, the poet tells us. He has a kitchen garden next to his hovel, where he leads water from nearby streams to his cabbages, beet, sorrel, and other plants. However, these are for selling at the local market. For his own use, he chooses garlic, parsley, bushy rue, and coriander.

Simulus sits again beside the bright fire and, with mortar and pestle, mashes the herbs, along with salt, the hard cheese, a little olive oil, and vinegar. Round and round goes his right hand, the original ingredients gradually losing their own properties and becoming one (or, in the poet’s Latin, *e pluribus unus*). Often the sharp smell goes right up his nostrils, so that he passes judgment on his dinner, while with the back of his hand he wipes his streaming eyes. He mixes and thoroughly remixes the mass. Finally, he wipes it out into a single ball, to produce a perfect *moretum*. With bread and *moretum*, he can leave to do the plowing, “with the fear of hunger banished, and free from care for that day.”

Simulus is an unusual domestic cook in being a man (perhaps the poet wanted a man to do women’s work to emphasize the lowliness of the scene). He appears to cook merely for himself (although he might live with an African woman, mentioned in the poem). He uses no obvious cooking pot. Otherwise, much else is universal. So much cooking throughout the world for perhaps 10,000 years has been done with a small fire, storage bin, water jug, stones for milling grain, and mortar and pestle for preparing herbs and spices.

Commentators have called the *moretum* a “country salad” and “herbed cheese.” However, the closest equivalent known to many these days is probably the Italian sauce of basil, parmesan cheese, pine nuts, and olive oil called pesto. His is a typical agrarian meal of two parts. The basic element is the staple, such as rice, potatoes, or cereals, which make the bread here. This is accompanied by a tastier, nutritional complement, which has commonly been something like the *moretum* prepared from vegetables and perhaps a little protein.

Wealthier people employed cooks to serve elaborations of such a meal. The foods have been more numerous, and more luxurious. Rather than a sauce accompanying the staple, it might have accompanied meat. Sauces not unlike the *moretum* are called the “trademark of the Roman chef” by classical scholar Jon Solomon (p. 115). Of the nearly five hundred entries in the Roman cookery book of Apicius, *De re coquinaria* (The Art of Cooking), he finds that nearly four hundred are devoted to the preparation of a sauce. They begin with the pulverizing of herbs and spices in a mortar. Fruits and nuts are then added, and finally, liquid such as water, honey,

oil, milk, mustard, or *liquamen* (a fermented fish sauce also known as garum). This mixture is often boiled over a fire, and sometimes thickened with wheat starch, egg, rice, and so on. For example, the dozen different sauces for lamb (or kid) include a simple bread and oil sauce, a sweet milk and date sauce, and a vinegar and plum sauce.

## Medieval Recipes

In some of the oldest recipes in English, numerous sentences instruct the cook to take one or more ingredients, using such archaic words as “tak,” “nym,” and “recipe” (giving the name for culinary prescriptions). Once cooks have “taken,” the same medieval recipes call on them to “grind,” “dyce,” “shred,” “mince,” “bray” (crush with mortar and pestle), “quarter,” “quare” (cut into squares), “swyng” (swinge or beat), “alye” (mix), and “medle” (mix). Heat is then used to “frye,” “parboile,” “boyle,” and “seeth in gode broth” (seethe or boil in a good broth). The recipes conclude with “serve it forth” or, which means the same, “messe it forth.” In summary, cooks “take” and, having “meddled” (mixed), they “send.”

## Babylonian Dishes

Babylonian scribes impressed the oldest surviving recipes onto three clay tablets in cuneiform 3,700 years ago. The tablets, which their French translator Jean Bottéro describes in an essay entitled, “The Most Ancient Recipes of All,” reveal a cuisine of striking refinement for such an early period.

The best-preserved tablet takes just seventy-five lines to give twenty-five recipes. One name, “Assyrian stew,” suggests it has come from the northern part of the country and another, “Elamite stew,” ascribes it to neighboring people. Most headings, however, indicate various bouillons of such meats as deer, gazelle, kid, lamb, pigeon, and perhaps rat. The instructions typically start with the meat of the title with other meat added, then water and fat, along with condiments and often thickeners. Here is an example:

Lamb bouillon. You need other meat too. Place in water. Add fat, salt as you wish, crumbed cereal cake, onion and *samidu* [not yet translated], coriander, cumin, leek and garlic. Serve. (Bottéro, p. 251)

The compressed style suggests aides-mémoires for professional chefs. The other readable tablet devotes 250 lines to just 7 recipes for various kinds of birds, both domestic and game. The recipes indicate many steps, numerous utensils, complex combinations, and sometimes as many as ten different seasonings.

From a tantalizing glimpse of a vast gastronomic literature around 4,000 years old, it seems that the ancient Babylonians took great care in balancing flavors in complete dishes. They did not just throw birds on the fire, but followed complicated recipes calling for as many as ten seasonings. Historian Jean Bottéro acknowledges that this was the cuisine of rich people, who had the “skilled

personnel, requisite cooking vessels and stoves, and money for expensive provisions” (p. 254). While the recipes were probably prescriptions for some kind of ritual, he presumes that domestic cooks turned out tasty and imaginative dishes, even if not quite so complex or varied.

### The LoDagaa

The ordinary meal of the LoDagaa people in West Africa consisted of one dish, “a single but filling dish,” which was much the same from day to day. The preparations were observed by anthropologist Jack Goody and summarized in his wider study of *Cooking, Cuisine, and Class* in 1982 (especially pp. 69–78). He reports that the dish came in two parts, which he calls “porridge,” made from guinea corn or millet, and accompanying “soup,” usually made from ground nuts or leaves of one type or another.

The preparation of meals, largely done by the women, took a long time because produce had to be transformed all the way from its original state. In the case of guinea-corn or millet, the grain had to be removed from the head, husked, and winnowed. The grinding was especially hard, and the women would lighten their work by singing songs and chatting. Other laborious tasks were the processing of shea nuts to make oil and the turning of cassava into a safe food (the prussic acid formed in cassava dissolves readily in water and is driven off by heat).

One advantage of the cassava root is that it can be kept in the ground. Women also laid out the fruits of the okra, pepper, and soup leaves on the roofs to dry before being packed away in pots and baskets for the empty season. The LoDagaa sometimes stored grain in its malted form for brewing beer later.

The women could now use matches for lighting the fire, although men might still make fire using a stone, a piece of iron, and kapok for rituals. “Like yeast, fire was one of those marvels passed down from hand to hand, the embodiment of communal living, difficult to start, easy to keep going, especially if one has kin and neighbours on whom to rely,” Goody writes (p. 70). The usual hearth consisted of three stones, on which the pots balanced. Virtually all the food was boiled. Fish and meat were occasionally smoked for preservation above the fire. Some frying was done, although more often in market for delicacies such as bean cakes. Corn cobs might be roasted, but roasting was more typical of meat and carried out by men. Baking was done in the new bread ovens in market towns.

Beer could be purchased in any of the LoDagaa markets. In fact, the evening markets seemed only to exist for beer and cooked food. Beer was also brewed daily at someone’s house. Women spread their days over their six-day week, so that today Brumo would brew, tomorrow Popla, and so forth. The men would often go to buy a pot, partly for the company.

Goody found that a conspicuous new feature of many African villages was the grinding mill, established by some enterprising trader and powered by a diesel motor. “Here women queue up to have their grain ground into flour, preferring to try and earn a little extra money in the market or by brewing beer, rather than undertake the heavy work of grinding by hand” (p. 69).

Numerous anthropologists have made similar field observations as those of Jack Goody. They have found tribal women devoting much of their day to fetching water, pounding roots, grinding grain, maintaining a fire, boiling a staple and its slightly more varied accompaniment, and perhaps using fermentation, as when brewing beer. Anthropologists have often noticed some tasks being done by specialists, such as bakers and tavern keepers, and the very presence of outside observers also suggests that agribusiness and related food industries will soon bring an even more centralized mode of preparation.

### Fast Food

According to one picture, the modern preparation of food is conducted by sophisticated corporations that employ advanced technologies to supply plentiful, healthy, tasty, and often “fast” food without tedious labor. According to an alternative version, high-pressure marketing promotes junk food that makes everyone fat, resulting from the heartless unloading of unskilled and dangerous work on youthful racial minorities.

Corporate historian John F. Love says in *McDonald’s: Behind the Arches* that the fast-food firm showered the “lowly hamburger, french fry, and milk shake with more attention, more study, and more research than anyone had dreamed of doing” (p. 120). But quality would appear to have lost out to other considerations. The main effort went into making the food easily handled and cheap. For example, all McDonald’s ground beef was frozen after 1968 (p. 130).

When McDonald’s System, Inc., was formed, french fries account for fewer than 5 percent of all potatoes sold in the United States, Love reports. By the mid-1980s, they accounted for more than 25 percent (p. 121). To maintain consistency, potato processors added sugar in one season and leached it out in another. This is one of the many findings described by investigative journalist Eric Schlosser in *Fast Food Nation* (p. 131). Fast-food chains abandoned skilled bakers in favor of automated factories, replaced farmers with scientifically managed batteries of chickens and feed lots of cattle, and coped with the uncertainties of chefs by doing away with them. For example, the firm of IBP (Iowa Beef Packers) led the revolution in meatpacking in the United States, by centralizing the slaughterhouses, by using cheap, often immigrant labor and, in Schlosser’s words, “by crushing labor unions and championing the ruthless efficiency of the market” (p. 164).

Armed with gas chromatographs and mass spectrometers, chemists synthesized a vast number of food

flavors by the mid-1960s. They manufactured the taste of Pop Tarts, Bac-Os, Tab, Tang, Filet-O-Fish sandwiches, and thousands of other new foods, according to Schlosser. When he toured the laboratories and pilot kitchens of International Flavors and Fragrances (IFF) in Dayton, N.J., he found a snack and savory laboratory responsible for the flavor of potato chips, corn chips, breads, crackers, breakfast cereals, and pet food. The confectionery laboratory devised the flavor for ice cream, cookies, candies, toothpastes, mouthwashes, and antacids. In one pilot kitchen, Schlosser saw a pizza oven, a grill, a milk-shake machine, and a french fryer “identical to those I’d seen behind the counter at countless fast food restaurants” (pp. 120–131).

Schlosser writes that “more than half of all American adults and about one-quarter of all American children are now obese or overweight. Those proportions have soared during the last few decades, along with the consumption of fast food. . . . The rate of obesity among American children is twice as high as it was in the late 1970s” (p. 240). One factor is the increasing size of fast-food servings. During the late 1950s the typical soft drink order in a fast-food restaurant contained about 8 ounces; now a “child” order of Coke at McDonald’s is 12 ounces; a “large” Coke is 32 ounces.

“Every day in the United States, roughly 200,000 people are sickened by a foodborne disease, 900 are hospitalized, and 14 die. According to the Centers for Disease Control and Prevention (CDC), more than a quarter of the American population suffers a bout of food poisoning each year,” Schlosser reports. “Although the rise in food-borne illnesses has been caused by many complex factors, much of the increase can be attributed to recent changes in how American food is produced. . . . [T]he nation’s industrialized and centralized system of food processing has created a whole new sort of outbreak” (p. 195). The “rise of huge feedlots, slaughterhouses, and hamburger grinders seems to have provided the means” for the deadly *E. coli* 0157:H7 pathogen to become widely dispersed (p. 196).

**PRESENTATION OF FOOD.** The presentation of food often refers to its visual composition on the plate, in a state of readiness to be eaten. Modern color photography has promulgated enticing artworks that have come to be the signatures of stylish cooks. All manner of theater is employed in the careful display of food to consumers, appealing to all senses, not just sight, and appearing not just at meals, but throughout the entire marketplace for food.

## Plate Presentation

Cooks often pay close attention to plate presentation, choosing ingredients and techniques to suit a desired effect, following a standard arrangement and wiping away drips. Some foods are included mainly to set off others, such as a parsley garnish, and such elements as shells are not to be consumed at all. Checking the food's appearance, which is the cook's last task, becomes the eater's first. Diners are often transfixed by the food when it arrives at the table, as if taking in the whole meal. Yet even the most impressive sculpture collapses at the strike of a knife, fork, or spoon, so that plate presentation is evanescent.

Vision is crucial in identifying ingredients, their quality, and the techniques used, and even has a bearing on the perception of flavor. A dish not displayed traditionally may "not taste the same," and an unfamiliar color, such as blue, may be off-putting.

Japanese diners recognize the importance of eye appeal, to the extent of photographing their meals at restaurants around the world. Their cooks display fanned slices, neat parcels, sculpted vegetables, and noodles placed in soups. Cut fish displayed without sauces contributes to a clean look. Chefs might "spend the day considering the aesthetics of arranging three sardines," according to Richard Hosking in *A Dictionary of Japanese Food* (p. 209). *Moritsuke* (food arrangement) follows seven basic patterns, including *sugimori* (strips and slices of food in a slanting pile), *kasanemori* (overlapping slices), *tawaramori* (blocks or rounds placed horizontally in a pyramid), and so on. Illustrating invention within a highly regulated framework, the *shojin ryori* cookery tradition arranges food like a seasonal landscape—perhaps blue mountains in summer, red in autumn, brown in winter, and flowery in spring. The resulting scene is so abstract that it may appear as one or two objects on a plate to the untutored eye.

As Japanese cooks and diners also appreciate, food is framed by the plate, which might be a beautiful object in its own right, and by the table setting; by other foods, including drinks; by decorations, such as flowers; and by a garden outlook or streetscape.

By contrast, some gourmands in the European tradition worry that an overemphasis on appearance downplays food's other qualities, notably taste and flavor. These cooks may contend that the visual aspect is food's most superficial and that the eyes are quickly contradicted by the tongue.

## Atmosphere and Setting

Even before seeing the food, diners might be enticed by menu descriptions. Cooks sell their efforts through sizzling sounds and enticing aromas, so that food is presented at the right temperature and dish covers removed to release captured smells. A charming dining room is comfortably warm and filled with the right music (which might be only the clink and chatter of dining itself). Pre-

The appearance of food on the table has changed greatly over time to reflect shifts in custom and tastes. In this plate from *Cassell's Household Guide* (London, circa 1878), various meat and fish dishes are displayed according to proper Victorian presentation—with heads attached. Garnishing is minimal because this style of food is intended for home cookery rather than for hotel fare. All of the meats except the calf's head are served in lakes of gravy. ROUGHWOOD COLLECTION.

sentation is also social, and servers participate through such means as well-spoken descriptions, the use of elaborate platters, and carving at the table. Food is also generally enhanced by a convivial circle; many good meals are enveloped in conversation.

Much effort goes into presentation away from the table, too. Market stall-holders stack food showily, shopkeepers arrange eye-catching window displays, and confectioners design luxurious-looking chocolate boxes. Hot bread, roasting chestnuts, and coffee sell themselves through aroma.

## Food Fabrication and Marketing

The modern industry fabricates foods from non-traditional ingredients and additives to look like a familiar product (margarine masquerading as butter; emulsifiers, thickeners, and artificial flavors masquerading as ice cream, and so on). Teams of brand managers, flavorists, marketing

specialists, graphic designers, and others devise new products, whose acceptance hinges on presentation. Advertising programs, promotions through free samples, discounts and prizes, and point-of-sale materials and packaging provide the final sales pitch. Marketing relies on supermarket shelf exposure, which is boosted by multiple sizes and flavors, and on food's photogenic qualities, which are geared to be so mouth-watering as to induce sales.

### Purpose of Presentation

The drive toward balancing colors and textures in front of the eater, experienced in all cuisines at least rudimentarily, has a nutritional basis: providing a healthy variety. Responding to contemporary dietary trends, cooks may include, for instance, green and orange colors in their presentations. Another source of the cooks' aesthetic impulse is the mixture and distribution of ingredients according to a routine or pattern. This repetition can lead to a pared-back elegance.

Cooks who want to show off ingredients find that presentation encourages inspection. Alternatively, in search of amusement, cooks may make foods look like something else, such as a fish made out of vegetables. Cunning cooks can contrive the look of expensive, forbidden, or unobtainable ingredients, and war-time rationing has encouraged such subterfuge. The profit motive comes in here, too, with growers and manufacturers employing many scientific means—from growth hormones to artificial flavors—to improve the appearance especially of cheaper and more readily handled products. Presentation can hide food's origins; some vegetarians contend that meat-eaters only find meat palatable when it no longer resembles “dead animal.”

In *The Civilizing Process* (1939), German sociologist Norbert Elias argues that the increasing complexities of society are accompanied by more self-restrained, courteous, and sophisticated culture, including refined food presentation. Demonstrating social power with extravagant displays is captured in American sociologist Thorstein Veblen's phrase “conspicuous consumption” (*The Theory of the Leisure Class*, 1899). Presentation can also symbolize a seasonal festival or other occasion, as in the historical development of the white, possibly tiered, and carefully decorated cake as the nuptial centerpiece. Cakes were first used for weddings in the seventeenth century and became the familiar gleaming structure in the nineteenth.

Food is styled to look good in photographs for mass-circulation newspapers, magazines, and cookery books. Many cooks also follow an artistic impulse beyond mainstream lifestyle publications, seeking to avoid last year's accents and playing a competitive game through fashion. Because the pressures to achieve elegance, pretense, camouflage, and artistic expression can spoil the final effect, critics have long demanded that presentation be simplified and that food should look more “real.”

### Ancient Lavishness

Elaborate presentation has its roots in ancient times. The Greek epicure Athenaeus describes lavish feasts, not uncommon in third century B.C.E. Macedonia, at which as many as twenty guests were crowned in gold tiaras and presented with silver cups to keep. Mountains of food were pressed upon them, accompanied by musicians, dancing girls, and drinking. A large pig was then carried in, its belly disclosing numerous birds and fishes. After more drinking, guests were served a piping-hot kid, with another silver platter to keep, as well as spoons of gold, and ivory bread baskets. Naked women tumbled among swords and blew fire from their mouths before crystal platters arrived with baked fish.

Such excesses were also frowned upon. Some of the mightiest medieval minds, including St. Thomas Aquinas, considered *gula*, or gluttony, the foremost of the seven deadly sins, and Chaucer's Parson inveighed characteristically against the “apparelling,” or dressing up, of food, which included pastry and aspic designs, marzipan armorial quarterings, meat dishes such as Cockentrice (the front half of a chicken sewed to the back half of a suckling pig, and vice versa), and “musician” pies that contained live instrumentalists.

Most famously, at seventeenth-century Versailles, under the “Sun King” Louis XIV, court life consisted of vast dinners enlivened by musicians and fireworks and the arts of conversation and good manners. The king, as the head of the household, lived in semi-public (“in state”), a crowd watching as he arose (*lever*), went to bed (*coucher*), and had meals in between. Parisians and provincials would come to admire Louis XV's fine bearing and elegance, and his deft striking off of the top of a boiled egg with the back of his fork.

Adapting the royal family's grandeur, the ambitious French chef Marie Antonin Carême published in *Le pâtissier pittoresque* (1815), one of the earliest of his several books, more than a hundred depictions of *pièces montées*, elaborate architectural pastry follies.

At table during the London “season” early in the nineteenth century, conversation was prevented by a “huge centre-piece of plate and flowers.” It was “strange that people should be invited, to be hidden from one another,” wrote the English advocate of a simpler “Art of Dining,” Thomas Walker, in his weekly newspaper, *The Original* (2 September 1835; 1928, p. 11), noting that fashionable tables required “excessive breadth” to hold the cumbrous ornaments and lights, the dessert with side-dishes. He opposed fussy cooking, especially “a very inconvenient love of garnish and flowers, either natural or cut in turnips and carrots, and stuck on dishes, so as greatly to impede carving and helping. . . . But there is a still worse practice, and that is pouring sauce over certain dishes to prevent them from looking too plain, as parsley and butter, or white sauce over boiled chicken” (1928, p. 14).

Perhaps all the singing, dancing, fabulous table displays, glamorous surroundings, and networks of diners and servants meant that presentation had overwhelmed the food. However, lavishness lent importance to the entire social and cultural event, a point recognized by the Parisian restaurant of the late eighteenth century, which attracted customers with mirrors, upholstery, and elegant service. Here individuals could order anything from a list at any time and even for a table of one, thereby narrowing the focus to what appeared immediately in front of them and giving rise to the modern fixation on the plate. In *The Invention of the Restaurant*, Rebecca Spang finds “a world in which eating was not a biological imperative but an artistic passion, and in which food came not from farm or field but from ornately decorated boutiques.” The new gastronomic writers hailed “the grand restaurant’s ability to stimulate and satisfy any desire” (pp. 150–151).

### Modernism

Fashionable food presentation moved toward a simplifying modernism during the twentieth century. Worshiping “the geometric splendor of speed,” the Italian branch of the Futurist movement under Filippo Tommaso Marinetti turned food into art in the 1930s. The Futurists advocated “optimism at the table,” accompanied by “experimentation with new, apparently absurd mixtures.” Believing that “form and color are just as important as taste,” they struggled against “puddles of sauce, disordered heaps of food, and above all, against flabby, antivirile pastasciutta” in an appeal to Italians to abandon pasta that captured headlines around the world (Marinetti, pp. 21, 36, 38, 67, 133).

French semiotician (scholar of signs) Roland Barthes ridiculed “ornamental cookery” in one of his *Mythologies* essays written between 1954 and 1956. The color photographs in *Elle* magazine sold a “dream of smartness” to the working class, he wrote. Shown from a high angle, at once near and inaccessible, the food could be consumed “simply by looking” by people who could dream of partridges but not afford them. Any actual food was “no more than an indeterminate bed-rock” beneath “sedimentary layers” of smooth “coatings and alibis.” For the “primary nature of foodstuffs, the brutality of meat or the abruptness of seafood” was buried beneath sauces, creams, icing and jellies. These coverings were the blank page for a “fairy-land reality” of chiseled mushrooms, carved lemons, shavings of truffle, and arabesques of *glacé* fruit.

French restaurant cooking returned triumphantly to the basics with nouvelle cuisine in the mid-1970s. The waiters were less likely to serve from silver platters (“flats”); instead, cooks positioned the food carefully in the kitchen and on plates about one-third larger, accentuating the lighter portions. The food was more geometrically laid out, relying on the natural colors of the primary ingredients with sauces underneath rather than on top. This less laborious food required more genius, and so was often copied badly. But the trend spread

quickly, largely because of its striking, somewhat Japanese look, originally photographed from above but increasingly from the side to benefit its often elevated constructions.

### Food for the Camera

Food that is cooked for the camera is captured by specialized photographers attuned to the fashion demands of art directors for billboards, television advertisements, magazines, and cookbooks. The focus, color, shine, and unreality of food photo spreads have earned the epithet “gastro-porn.” Because posed food will wilt, shrink, go soggy, dry out, and lose its gloss under the lights, “food stylists” are just outside the shot, coaxing food into pleasing shapes with tweezers, syringes, sprayers, and dry-ice. They employ refillable butane blowtorches and paint strippers to help with “cheese melts” and browning. The stylists employ hairspray and jars of Aqua Gel to make realistic-looking water droplets or to thicken sauces. Since the food is to be seen and not eaten, mashed potato might masquerade as ice cream.

Dishes, such as one-pot stews, that do not photograph well may have their recipes excised. Cuisines, such as those of India, may be considered unfashionable, because they have typically been arranged in several dishes, any one of which might look somewhat nondescript.

In turn, cooks can become overly inspired by brilliant photography. But they should be careful not to make food seem too good to eat, as if it were some untouchable work of art, as the German sociologist Georg Simmel warned in his 1910 essay on the meal. Good presentation can contribute greatly to, but should not be allowed to distract from, either conviviality or the appreciation of the food’s natural roots.

**PRESERVING.** Food preservation conserves food for future use. Most of the basic processes have been employed throughout the world for millennia. The primary methods of salting, canning, drying, pickling, smoking, salting, fermenting, cold storage, and freezing all provide an extreme environment in order to stabilize the food for later use. Although most of these methods are used both commercially and in the home, the basic techniques are the same.

### Early Methods of Preservation

The idea of preserving food for future consumption was probably first practiced by storing it in a secure place. Original practices mirrored natural processes, such as cold storage, freezing, drying, and even fermentation, which can naturally occur in fruit. Food preservation is evidenced in the archaeological record and in early written records, which indicate the use of salt, snow, smoke, pickling, drying, and fermenting. Ancient Mesopotamia, Egypt, Greece, and Rome all practiced many of these methods of food preservation. Evidence from a Chinese tomb dating prior to 2,000 years ago gives instructions on inscribed bamboo for salting, drying, and pickling. Sixteenth-century records from the observations by the European conquerors of the Maya indicate the use of smoking to preserve peppers and other foods. Methods of preservation like sun drying, smoking, and salting might have been used very early on to preserve the most perishable types of food, such as fish.

Salt, naturally occurring in deposits or as evaporated seawater, could have been dissolved in water as a brine, or in combination with other processes, like drying and smoking, could have preserved many foods. Some foods were not edible in their natural state, like certain tubers or olives, and would have required brining. Grains in particular, once harvested, were probably kept for consumption throughout the year and as protection against the failure of a future harvest. Storage in a dry and cool environment would have prevented molds and sprouting of grains. Fermentation of grain to make beer and of grapes to yield wine can preserve a large and perishable crop.

Early food preservation included simple "banking" in pits, which were dug in the ground and lined with various substances like wood, straw, and leaves to create a barrier between the soil and the food. Caves and storage vessels that were buried or sunk into the ground were also used to create a secure storage environment for the food. Food could be stored in skins, baskets, pottery vessels, or special structures built for certain commodities like grain. Liquids required a much more specialized container, and large supplies of certain commodities, like olive oil, beer, and wine, while difficult to transport, were valuable trade items, and required secure seals to protect the quality of the contents.

Pests, insects, damage from weather or moisture, molds, fungus, decomposition, or a combination of these factors lower the quality of or even destroy the food, and these factors had to be taken into account. Whether the food preserved is being held to guard against future crop or harvest failures, for trade or barter for other commodities, or to divvy out certain foodstuffs as part of the yearly diet, the quality of the food preserved had significant impact upon the future quality of life.

### Canning

Canning refers to a technique used both commercially and in the home to preserve food in sealed containers. In the early twenty-first century, metal cans are used commercially and glass jars are used in the home. The concept of preserving foods by cooking them and then sealing them in a container is ancient. Olive oil, lard, wax, pitch, clay, and skin have all been used to seal vessels containing food, but are not very reliable. In the late eighteenth century, France offered a monetary award for a method that could be used to preserve food for soldiers. After years of experimentation, Nicholas Appert successfully used sealed glass jars, whose contents had been thoroughly cooked in a water bath, to create portable and potable food. He was awarded the prize in 1809 for his work and went on to publish his findings in "*L'art de conserver pendant plusieurs années toutes les substances animales et végétales*" (The art of preserving all kinds of animal and vegetable substances for several years). In 1810, Englishman Peter Durand received a patent for the same process but included tin containers as well as glass.

Tin containers had been used for food storage previously, but it was the combination of the water bath and the sealed container that was so successful. Initially made by hand, tin-plated cans sealed with lead solder were used. By 1819 the Arctic explorer William Edward Parry had included canned foods with the expedition supplies, but the discovery in the 1980s of some of the bodies of those lost on John Franklin's last Arctic expedition in 1847 and their analysis in the 1980s and 1990s indicates that they were suffering from lead poisoning from the lead seals in food cans. Food cans manufactured in the United States have not used lead solder since the mid-1990s, but canned food products from other countries could contain lead solder.

In the United States, various individuals worked on streamlining tin can production, improving the methods of canning various foods, like corn, tomatoes, and lobster. During the mid-nineteenth century in the United States, both commercial canning and home canning expanded, driven by the demand for product by the westward expansion of settlers. The armies of the Civil War used canned goods. Another significant milestone was canned condensed milk, which provided canned milk that was safe to drink, and was developed by Gail Borden in the mid-nineteenth century.

As more foods became available in cans, home cooks “canned” in glass a wide variety of products using basically the same techniques. In both commercial and home canning critical factors were sufficient temperature, sterile containers, and an effective seal. John Mason patented a glass jar with a screw cap to seal it in 1858; numerous patents followed for a reliable and effective seal. The consequences could be illness and even death from bacteria that could grow inside the container, generally the naturally occurring botulism bacteria (*Clostridium botulinum*). Invented in the early twentieth century, the new and most common jar closure used today has two parts that separate the jar cover from the threaded ring. Commercial canned goods created a dependable and transportable food, and are used extensively by consumers all over the world. Canned soup, tuna, juice, corn, tomatoes, and condensed milk are some of the most popular canned foods. In the United States, the cooperative agriculture extension service of the USDA is a source of accurate and inexpensive advice on all types of home preserving. Home canning has diminished in the United States as families moved away from their source of food, but in a 1996 survey, 56 percent of all U.S. households said they had canned in the past, of whom 28 percent had canned within the last two years. Although pressure canners are considered safer, many still use the conventional water bath for home processing.

## Drying

Drying occurs naturally with food left in the sun, or on the vine, like beans, or grapes. Some foods, like apples and tomatoes, are generally cut into smaller pieces for drying, a practice which allows the moisture to uniformly evaporate. Herbs are frequently dried whole and on the stem. Low humidity, heat, and air circulation are important so that mold does not occur. Meats and fish can be dried to the point of extreme desiccation, resulting in a product usually called jerky. Drying racks, screens, bags, strings, and bunches can be dried outdoors or in a warm dry spot indoors. Ovens or specialized equipment like dehydrators can be used to create the low temperatures necessary. Once dried, foods can keep for up to a year in a cool and dry environment. Dried foods are sometimes additionally smoked or salted.

Dry storage is usually used for grains, whole vegetables, and fruits like potatoes, onions, carrots, apples, pears

and turnips, herbs, and chilies. By keeping the food whole, at certain temperatures, with low humidity, in the dark, and pest-free, supplies can last for months, or years. While dry storage is sometimes in separate structures, dried food can also be stored in root cellars and cold rooms below ground or partially below ground.

## Fermentation

Fermenting produces beverages like wine and beer and foods like cheese and bread. Fermentation can occur naturally and with naturally occurring yeasts, or lactic acids. Early records in the Sumerian language indicate the manufacture of both beer and bread. Ancient wine making uses yeast and bacteria to transform raw material into the fermented beverage. Fermentation is the result of enzyme activity, naturally occurring proteins present in the food, or can be introduced into it. Sauerkraut and fermented vegetables, like the Korean dish *kimchi*, are produced with lactic acids. The cabbage, vegetable, or mixture is salted and placed in a container where it will ferment, creating an acid environment that will preserve it. This fermentation process is called pickling, just as the use of vinegar and the use of brine are also called pickling.

Vegetables can be very difficult to preserve without processing, but a wide variety of vegetables can be preserved by the addition of salt, after which the juices then drain from the vegetables and ferment. Certain sausages, vegetables, yogurts, and cheeses are all preserved by fermentation. Louis Pasteur's wide-ranging research, which included studying the fermentation process in wine and beer making, led to pasteurization and also to the theory that bacteria existed. The presence of harmful bacteria explained why food preservation had to follow very strict aseptic guidelines, or the food could become spoiled, inedible, or at its worst deadly.

The origins of yogurts and cheese are frequently explained as the result of milk being stored in a skin and warmed, which caused the milk to ferment, and separate into solids and liquids, or curds and whey. Through the use of lactic acid, salt, and heat, and by draining the liquids, cheese is created. By draining, application of pressure to remove the moisture, and by aging cheese can be held for years. Butter can also be preserved with salt. The quantity of salt necessary to preserve butter was such that early instructions required that the butter be washed before use. Unsalted butter is more perishable and has a different flavor.

### **Cold Storage**

Cold storage or refrigeration slows down decomposition of food. Initially, cold storage used natural snow and ice usually kept below ground and covered with straw, or branches. Snow was usually compressed to slow melting. In much of the ancient world, snow and ice were harvested, stored, usually in pits, and used in the summer.

Melting and storage were continuing problems. Much time and effort were devoted to solving these problems over the centuries, but it was in the nineteenth century that many technological advances occurred. In 1803, a Maryland farmer patented an insulated icebox using layers of insulation with charcoal dust. Icehouses were generally below ground structures, although circular brick ones were also used, and filled with layers of ice. In 1827, a more efficient horse-drawn ice cutter was invented for cutting natural ice off lakes and rivers. By the 1840s refrigerator railroad cars were in use in the United States. Around that same time various advances were made in artificially creating ice and refrigeration. John Gorrie, a physician in Florida, received a patent for ice manufacture in 1851. The technology existed, but the product was too expensive compared to natural ice. However, after the blockade of the South and the Civil War, artificial icehouses began to open. For example, the steam-operated Louisiana Ice Manufacturing Company opened in 1868, selling ice for \$1.75 for a hundred pounds. By the 1880s ice plants were located throughout the United States, but natural ice was still sold as well. In the twentieth century, ice became universally accessible. In 1913, the first home refrigerator became available and by the 1940s, 56 percent of all U.S. kitchens had electric refrigerators.

### **Freezing**

Freezing food originally took advantage of natural freezing, or below freezing temperatures, but artificially freezing food is an ancient practice as well. Frozen foods are quite stable, although flavor and texture may change. Experiments in compression and condensation led to mechanized ice production, and improved efficiency eventually dropped the price of artificial ice, so it was competitive with natural ice. Home machinery initially stored the ice needed to cool the food. Today, automatic ice and frozen food storage are present in most homes. Clarence Birdseye is generally credited with creating the commercial market in frozen foods, based on his experience with fish in the Arctic. After some years of experimentation mainly with fish, he had perfected his process by 1924, and coupled with advances in freezer cases in stores, frozen foods became widely available.

Freeze-drying is thought to have originated in Peru where the potato has been cultivated for about nine thousand years. At high altitudes, the potato harvest was spread on the ground and exposed to extreme cold and then pressure was applied to remove all moisture. Like other dried products, water is used to reconstitute the dried potato. Freeze-dried coffee was developed in the 1930s, and the United States space program used freeze-dried foods because of their light weight and stability for the astronauts' meals.

### **Irradiated Food**

Irradiated food is exposed to radiation from gamma rays or electron beams or X-rays to kill bacteria, insects, and parasites and reduce spoilage. NASA irradiates food used by its astronauts. Irradiation of food began in 1963, and in addition to the United States, a variety of countries use irradiation for food, including Russia, France, China, and South Africa. Currently, some fruits, vegetables, spices, and meats are irradiated and must be marked with an international symbol called a radura and sometimes a statement such as "irradiated to destroy harmful microbes."

### **Pickling**

Like many of the terms used in food preservation, the term "pickling" can mean several things. It can be used for preserving vegetables, fish, or meat with an acetic acid, or a vinegar. It can also be used to refer to a salt solution, or brine. Generally, it is used to describe the use of vinegar, spices, and salt to preserve vegetables, herbs, and fruits.

Salt is used as a dry packing material or dissolved in water as brine. In both cases it removes liquid from the meat, fish, plant, or dairy product, and prevents decay. To salt for preservation is to use salt to remove the moisture from the fish, meat, or vegetable. The brining method uses salt that has been dissolved in water. The salt is sometimes mixed with sugar and spices. Fish may be hung to dry afterwards, and can then be smoked. Salted codfish is still popular and widely available in spite

of pressure on the diminishing population in the Atlantic Ocean. Cuts of meat can remain in the dry cure for a period of time based on weight, usually about twenty-five days, and then are frequently smoked.

Brining is a similar process, with water, salt, sugar, and spices as usual parts of the brine. In brining, it is very important that the meat stays below the surface of the liquid. Time in the brine is related to weight, and the brine must be checked regularly to ensure that it is stable. Temperature fluctuations or insufficient salt can result in the loss of the ability of the brine to preserve the food, and decomposition can begin. The first evidence of this is usually the formation of a mold or "scum" on the surface. Early directions all indicate that the barrels or containers should be checked daily for this reason. Vegetables can also be preserved in brine, or with a dry salt coating. Anchovies, butter, capers, lemons, and herbs, even eggs are also commonly preserved with salt. Salt is also used to produce extremely concentrated and highly flavored sauces, particularly of soy, and/or fish, which have been in use since antiquity and were extremely important for flavor. The Romans had *garum* and other sauces, and the Chinese had soy sauce, for example. These condiments have modern counterparts in soy sauce, hot pepper sauce, fish sauces, and Worcestershire sauce. The purpose of all of these concentrated sauces, ancient and modern, is to carry an extremely dense flavor and saltiness into foods. Sweet flavors, in preserved fruits, were intensified by the combination of sugar and concentration through cooking.

### Smoking

Smoking is frequently used in combination with salting. For example, the ancient Mayans preserved chilis, as well as fish and meat, by smoking; in his treatise "On Farming," Cato describes salting and smoking a ham. Smoking takes two basic forms, hot and cold. In cold smoking, the purpose is to impart flavor, not to cook the food, whereas in hot smoking, the appropriate temperature for the fish or meat is necessary to "cook" it.

### Sweeteners

Early sweeteners included honey and syrups made from grapes, figs, or dates. Sugar made from cane was costly, but it became more available by the sixteenth century when the sugar plantations that were planted in the Caribbean and South America became major producers. Beet sugar was also in production by the nineteenth century. In preserving with sugar, fruit and a sweetener are cooked together until thickened and then packed into containers. Sometimes are included pieces of the fruit, and other times the mixture is strained and just the resulting liquid is kept. Whole fruits can also be cooked in syrup, until they have completely absorbed the sugar, and then left whole and eaten as a confection.

Our sense of taste identifies flavors as sweet, sour, salty, bitter and some say, *umami* (or savory). The major

preservation techniques utilize these very flavors, creating the core of our palate.

Daphne L. Derven

**PROFESSIONALIZATION.** Professionalization in food preparation, food media, food styling, restaurant training, and food production assures the consumer that professionals incorporate current educational and practical experience in foods, and possess unique knowledge and skills that solve particular problems facing the food industry. The food professional's goal is to take a body of abstract knowledge and effectively convert it into comprehensible terms for the public. Through the ages, specific knowledge about food was passed first from families, through guilds, and then to professional associations.

In the third century B.C.E., Rome's citizens handed grain to professional bakers (a practice that continued through the thirteenth century), yet bread baking also continued to be done at home. Before the second century B.C.E., Greek observer Athenaeus reported seventy-two kinds of bread in Greece. Rome's culinary advantage was based on outlying regions with efficient trade and transportation; it benefited from pickles from Spain, lemons from Libya, and peaches from Persia. In Rome a good cook was considered an artist, manipulating out-of-season foods. Yet after the appearance of the cookbook of Marcus Gavius Apicius, a first-century Roman epicure, no European cookbooks were issued until the thirteenth century. Historian Michael Symons associates this lapse with the influence of Plato, who warned against taking an interest in cooks. But by the twentieth century, Western scholars had become food specialists writing for public consumption.

Apicius's emphasis on the over-dramatization of the act of eating is what professionals are continually in danger of reproducing. Romans cooked for the eye, not the palate. In the fourteenth and fifteenth centuries, an emer-

gence of food-related trades was represented by guilds that secured exclusive rights to prepare and sell food products previously managed by journeymen. The French Revolution of the eighteenth century gave birth to the modern restaurant, transferring the art of cooking from courts to the middle and working classes, which signaled the death of the guilds. Modern-day restaurants have become, according to food historian W. K. H. Bode, "dormitories for the food manufacturing industry" that "sell their wares under long-established and well respected culinary language which have taken chefs . . . much toil" (Bode, pp. 233, 237). Modern man eats better, but he knows less about the preparation and presentation of food.

During the 1800s and 1900s, increases in population and food production stimulated the world economy with automated technology and mass-production marketing. Georges-Auguste Escoffier's introduction of the brigade system in kitchens broke down the craft barrier and gave rise to the appearance of assembly lines. Cooks became highly specialized, and cooking was corporatized. In eighteenth-century Britain, James Boswell, the literary biographer, defined man as a "cooking animal," noting that it is not tool making, but cooking that separates humans from nature. In pre-Christian Rome, sixth-century Italy, seventeenth-century Europe, and the present millennium, Western consumers did not worry about regional or seasonal limitations because with affluence and a good chef one could have what one wanted all year around.

The influence of cooks on society includes the areas of arts and technology. Before 4000 B.C.E., food was gathered by cooks; later, it was distributed by cooks; and in the last century, cooks organized foods, their efforts garnering professional recognition. Professional cooks were born from home cooks, a tradition that has been replaced with science and technology, a manipulation of foods. The advances that man has devised have changed the shape and taste of food consumed. Taste buds are no longer educated to distinguish the purity of foods.

Over time, food professionals have practiced by creating a recipe, consuming time and money, and refining it for specialized consumption. In the evolution to saturating foods with sauces and producing presentations merely for display, many food professionals disregarded primitive tastes based on indigenous products and cooking equipment made of local wood, fiber, and clay. Artisan work, craft in all phases of food preparation, fell more and more to cultivated specialists, who closely guarded their craft. As specialists begin to exert their knowledge more broadly, professionals may no longer dominate the foreground. The more knowledge is shared, the larger the impact on the profession that was founded on formalized techniques and apprenticeships.

Specialists who share their skills contribute to decisions on dietary needs by emphasizing less, but better-quality, healthy, safe, ecologically sound foods that exhibit global concern and may re-awaken consumers'

faith. Professionals “revisiting” food through the specialist “eye” learn from the past, and from global, urban, and rural foods.

Some philosophers contend that thinking of food as a movement changes its significance. The recognition by other professions of the significance of making food can dispel ignorance and disrespect of food and enable research into such subjects as bioterrorism in the food supply. Our identity with food is transformed at the speed of technology, and food specialists, by sharing skills and information, help manage this transformation that shapes our history and forms our future.

**PROTEINS AND AMINO ACIDS.** The average human body, weighing 65 kilograms, contains about 11 kilograms of protein, 40 kilograms of water, and 9 kilograms of fat. The protein provides the “machinery” of the body, including not only the voluntary muscles and the heart muscles, but also the walls of the gut and the

blood vessels, as well as the enzymes, the skin, and the hair. The word “protein” is used to describe a group of different compounds with varying properties—soluble, insoluble, and so on. Originally they were classed together because, unlike fats and carbohydrates, proteins also contain nitrogen in addition to carbon, hydrogen, and oxygen. Now, we know that they are all composed of chains of “amino acids” linked together like enormous necklaces of thousands of individual beads. To continue the analogy, there are twenty different varieties of “bead” (or amino acid). The chemists’ shorthand representation of the common formula for each amino acid is “H<sub>2</sub>N.CHR.COOH,” where “—H<sub>2</sub>N” is the basic amino group, “COOH” is the organic acid group, and “R” the general symbol for whatever additional group is present for that particular “bead.” Amino acids can form chains by reaction between the amino group of one molecule and the acidic group of another to give:

The body makes its own proteins and obtains amino acids from the digestion of the proteins in the foods that we eat. These large protein molecules cannot be absorbed through the gut walls into the bloodstream, but a series of digestive enzymes (which are proteins themselves, having these special digestive functions) break down the chains of amino acids into the individual amino acids, which are then absorbed. A small proportion of protein may remain undigested, especially with the more fibrous plant foods such as bran, where the cellulosic cell walls are not easily broken down in the tissues, but, for most mixed human diets, one can assume at least 90 percent protein digestibility.

The final nutrients that we obtain from our foods are thus amino acids rather than proteins, and we build our own protein “necklaces” up from the pool of free amino acids circulating in our body. This pool is also derived in part from body proteins that are continually being broken down and resynthesized. Our bodies are in a dynamic state and are constantly turning over.

Each protein in our body has a specific function and is made up of a predetermined succession of amino acids that, when the protein is being synthesized, are added one by one to the chain. If a particular amino acid is missing from the site of synthesis, the process stops. Of the different varieties of amino acids, some are termed “essential,” which means that our bodies are unable to synthesize them by modification of another molecule. Four amino acids in this category are lysine, methionine, threonine, and tryptophan. Others, the “nonessential” amino acids, can be made in the body from other nitrogenous compounds.

#### Protein Functions

Obviously, a growing body needs dietary protein in order to increase its own body tissues. This is particularly

clear in species where the young grow quickly, such as calves and particularly piglets, and it is interesting that the dams' milk in these species is considerably higher in protein than is human breast milk, the natural food that meets the needs of much more slowly growing human infants. It is also obvious that older children need protein for their continued growth and that pregnant and lactating women need it to provide for the growing fetus and then for the suckling infant. The protein needs of other adults are not so obvious, except for the slow but continuous growth of hair and fingernails, the replacement of rubbed-off skin, and other minor losses. However, adults require much greater amounts of protein than would be expected to replace these losses—something like 50 g/day.

It is true that living tissue is in a dynamic state, with protein being continually broken down to its constituent amino acids and resynthesized, but this should not increase requirements because the amino acids are fully available for reuse. However, there are enzymes in the liver whose function is to break down an excess of circulating amino acids. These enzymes allow the elimination of nitrogen in the form of urea and the utilization of the carbon-containing side-chains of the amino acids as energy sources for the tissues. It appears that what we might call the "idling rate" of these enzymes sets the requirement for amino acids to replace those lost in this way. In the course of evolution there has presumably been no advantage, in general, in selecting for individuals with lower "idling levels" because protein intake was not a limiting factor. However, evolutionary selection may explain the apparently lower protein requirements of natives in an area of Oceania with a traditionally low-protein diet.

At one time it was thought that the muscular contractions required in any kind of physical work consumed protein, as if the muscle used itself up or was its own fuel. We now know that this is not the case, and that carbohydrate and fat are the normal sources of the energy required for physical work. The erroneous belief that physical work uses up protein has, in the past, been of some practical import since it meant that traditional working-class families would give a large proportion of what meat was available to the "breadwinner" father because of his greater physical labor, so that little remained for the others even when the wife was pregnant and her requirement for more concentrated sources of nutrients was actually more critical.

### Protein Levels in Foods

From the preceding discussion, it is obvious that meat from other animal species is a rich source of protein. The only qualification is that fat can seriously dilute the concentration of protein available. Lean muscle has a 3:1 ratio of water to protein, whereas fats are laid down without associated water. Thus, a cut of meat with 20 percent fat will also have only 20 percent of protein (that is, 1/4 of 80 percent). Further, since fat provides 9 Calories of en-

ergy per gram and protein only approximately 4, it follows that 9/13, or approximately 70 percent, of the energy provided by the meat will be coming from animal fat. (Note that the dietitian's Calorie, spelled with a large "C," is one thousand times the standard "calorie" and is the heat needed to raise 1 kilogram of water by 1°C).

The working parts of plants, principally enzymes, also consist of proteins; and seeds always include protein that will be required for the synthesis of new tissues when the seed germinates. In general, the concentration of protein is lower than that in animal tissues because the structural components consist of fibrous carbohydrates and, for seeds or root stores, large amounts of starch and sugars are usually also present as a reserve of energy.

There are several different ways of comparing the relative richness of different foods in protein. The simplest way would be a straight comparison of the percentage of protein in each food. Thus, whole milk contains just over 3 percent while white bread contains 8 percent or a little over, that is, more than twice as much. Yet the dietitian's practice when considering adult-type menus is to compute the quantity provided by a typical "serving." Thus, for milk the standard serving is 1 "cup" (245 grams), which provides 8 grams of protein. If we take two slices (50 grams) as the standard serving for white bread, this provides only 4 grams of protein, that is, less. So, there is a contradiction. Milk, of course, is nearly 90 percent water. Dried whole milk contains 27 percent protein and dried bread only 13 percent. This is perhaps a fairer comparison since one would consume more water with a meal if one were not drinking fluid milk, and it leads to one finally regarding milk as being the richer source of protein.

Common refined cereals (white flour, white rice, and de-germed cornmeal) all contain about 10 g protein per 100 g dry matter, with wheat providing a little more and rice a little less, as do potatoes. Lean fish and meat have up to 60 percent protein in their dry matter and skim milk has 40 percent. Among plant products, the legume crops (peas and beans) have the highest values, commonly 20 to 25 percent of dry matter. Legumes that are rich in fat (the so-called oil-seeds) can be processed to remove the oil, and the residues have even higher protein values. Extracted soybean meal has 45 percent protein and materials of this type have been used to make vegetarian substitutes for meat.

One would expect that the wealthier countries, with their greater use of animal products of high protein concentration, would have overall diets of higher protein content, but this is not always the case. Wealthier population groups also consume higher levels of fat and sugar, much of them in fast foods and "cola-type" drinks. These dilute the protein concentration of the diet to the levels of those poorer countries whose diet is based on cereals with less in the way of supplementary foods of either high or low protein content.

A particular problem exists where a poor community has plantains and/or cassava (manioc) as its staple foods. These have only about 2 to 4 percent of their dry matter in the form of protein, that is, values much lower than the corresponding value for grains. In addition, these foods are so bulky that young children being reared on them are commonly unable to consume enough to meet even their energy needs. They are thus at constant risk of both protein and energy deficiencies and should be given more concentrated foods.

### Protein Quality

As mentioned above, if a human diet were to be totally deficient in one essential amino acid, a child would immediately cease to grow and even an adult would go into decline. In practice this never happens. Even though one can extract from some plants an individual protein that is of this kind (for example, the gluten present in wheat), the total mixture of proteins in any natural food contains some of each of the amino acids, though not usually in the exact ratio in which the human body will use them. This is not a problem so long as the essential amino acid is present at the lowest level that is adequate to meet the body's need for it. The remaining amino acids will conversely be present in excess, and, as explained in the previous discussion, mechanisms exist to metabolize these amino acids to provide an additional source of energy.

Providing fast-growing young rats with wheat flour as their sole source of protein in a diet that is otherwise well balanced, will result in relatively slow growth; rats fed on the same diet supplemented with a small quantity of the amino acid lysine will grow considerably faster. Under these experimental conditions, the protein of wheat flour is said to have a low "biological value" and its "limiting amino acid" to be lysine.

Mixtures of foods that have different limiting amino acids can supplement each other. Thus, if one protein source, such as a grain, is limited by its lysine content, but has methionine in excess, and another protein source, such as a legume, has a good level of lysine but is short of methionine, a mixture of the two will have a better balance than either alone. This phenomenon can be clearly demonstrated in experiments where young growing rats, for example, are fed a mixture of wheat flour, primarily deficient in lysine, and navy beans, primarily deficient in methionine. Young rats grow faster when they are fed with both wheat flour and navy beans, as opposed to being fed with either protein source separately, but still not as well as when they are fed with well balanced egg protein because the mixture is still partially deficient in a third amino acid, threonine.

There has been a great deal of research and controversy about how serious partial deficiencies of individual amino acids are in human diets. In poor communities in North Africa wheat has been the traditional staple food, with only small quantities of supplementary foods. When synthetic lysine became available at a reasonable cost, a

trial was carried out to determine if fortification of the traditional diet with lysine at the time the grain was milled would result in improved vigor in people and in improved health among children. However, there was no evidence of any benefit. Nor was any benefit seen in comparable trials in Thailand.

It is clear that the young rat can be a misleading model for humans. A child grows much more slowly to its adult size than a small animal and, at its fastest rate of growth, adds no more than 3 grams of protein to its tissues in a day—a very small amount in relation to its protein intake, which would normally be ten times as great even with a diet containing no more than 10 PCal%. A more common problem than diet based on grain that is deficient in an essential amino acid, is the fact that people do not eat enough to cover their energy needs—in adults, because of poverty in most cases; and in young children in the developing world because their food is too bulky for them to be able to consume all they need. In such cases adults can lose muscle power and general vigor and small children can develop kwashiorkor, a potentially fatal disease that appears to be a combined deficiency of energy and protein, because what protein is ingested has to be used as additional fuel.

### Vegetarian Diets

It is clear from what has been written already that vegetarians can have an adequate intake of protein, particularly if they are willing to consume milk and eggs which provide good supplements to the protein of grains, and do not require animals to be killed. Vegans, who eliminate all animal products from their diets, commonly ensure that, in addition to consuming grains, they have a good intake of legumes as a supplementary source of proteins relatively rich in lysine. The legumes may not always be essential, but the supplementation provides a useful safety margin. The long-term problem for vegans is that they will become deficient in vitamin B<sub>12</sub>, unless they take a special vitamin supplement, because this vitamin occurs naturally only in animal tissues or from the fermentation of certain bacteria.

### Protein Requirements.

The recommended daily dietary allowance for an adult of average build is 0.8 grams of protein per kilogram of body weight, equivalent to 0.36 grams of protein per pound of body weight, regardless of sex. Since "average" men and women in the United States are assumed to weigh about 170 and 130 pounds, respectively, these standards give us an intake of 61 grams protein for the average man and 47 grams of protein for the woman, with a further addition of 15 grams of protein per day for women during pregnancy and lactation. These standards were designed to be adequate for diets containing protein of average quality and to contain some margin of safety. Virtually all American diets contain more than this amount of protein.

Despite children's need for growth, their requirement for protein as a proportion of their total food is lower than that of adults, because their energy expenditures in relation to their size are greater than those of adults, and their growth is so gradual. However, if a child's appetite is very poor and/or the diet is very bulky, the diet can become protein deficient because some of the small amount of protein consumed will be used as an energy source.

**PROVERBS AND RIDDLES.** Proverbs and riddles are pithy verbal expressions handed down over the course of many generations. Both forms are grounded in the familiar, but in opposite ways. While proverbs tend to re-familiarize the familiar, riddles tend to de-familiarize the familiar. More specifically, proverbs function like mini-allegories by embodying an abstract truism in concrete imagery drawn from familiar experience; the truism is thus reified and made "extra-familiar." For example, in the sixteenth century, the abstract truism "change occurs gradually" was reified in a vivid proverb that invoked a familiar domestic situation: "Little by little the cat eats the bacon." In contrast, riddles cause their reader to see an ordinary object in a new and extraordinary light. For example, the riddle "A little white house without door or window" prompts the reader to re-apprehend the thing implied by the riddle: "an egg." In the moment that this solution is guessed or given, the egg is perceived not merely as something to fry or hatch, but as a home or shelter, an analogue to the reader's own house. Because riddles and proverbs alike are grounded in the familiar (albeit in different ways), food and culinary situations supply the raw material of many of them.

#### Food Proverbs

The study of proverbs is called paremiology. Some paremiologists distinguish proverbs from maxims, saws, sententiae, and other kinds of folk sayings, but in practice these distinctions are hard to maintain. In this article, the term "proverb" is employed in its widest sense.

Over the centuries, food proverbs have enjoyed and suffered the same vagaries of popularity as proverbs in general. In ancient times, proverbs were much esteemed,

as evidenced by the Old Testament Book of Proverbs, which includes many food-based maxims such as "Eat thou not the bread of him that hath an evil eye, neither desire thou his dainty meats" (23:6). Aristotle, too, is reputed to have written a work on proverbs, now lost. During the Middle Ages, sermons and other didactic works popularized hundreds of proverbs, such as "He must have a long spoon that shall eat with the devil," first recorded in 1395. During the sixteenth century, numerous ancient Greek and Latin proverbs were revived thanks to the Dutch humanist Erasmus, who published a collection of three thousand proverbs derived from classical literature, including "You are decorating a cooking pot" (meaning "You are doing needless work") and "When offered turtle-meat, either eat or don't eat" (meaning "Make up your mind, one way or another"). The popularity of proverbs among learned authors increased through the seventeenth century, but then began to decline in the eighteenth century, when they came to be seen as evidence of vulgarity rather than erudition. In 1741, for example, Lord Chesterfield belittled "common proverbs" because they were "proofs of having kept bad and low company. For example, if, instead of saying that tastes are different . . . you should let off a proverb, and say 'that what is one man's meat is another man's poison' . . . everybody would be persuaded that you had never kept company with anybody above footmen and housemaids." (461)

Proverbs about food reflect, naturally, the gastro-nomic and culinary norms of the culture in which they arise. For example, the proverb "from eggs to apples," meaning "from beginning to end," originated in ancient Rome, where it was customary to begin a meal with eggs and end it with apples. In China, proverbs abound that mention rice or tea, including "Talk doesn't cook rice" and "Better to be deprived of food for three days than tea for one." In Azerbaijan, many proverbs refer to yogurt and halva, including "He who burns his mouth on milk will blow on yogurt when eating it" and "Your mouth won't get sweet just by saying 'halva.'" In Germany, where wine-making is common, one encounters the proverb "Big and empty, like the Heidelberg tun," an allusion to a wine cask renowned for its 58,000-gallon capacity. In England, the prevalence of proverbs involving eggs attests to the long-standing importance of that foodstuff in that nation's diet; *A Dictionary of the Proverbs in England in the Sixteenth and Seventeenth Centuries* cites twenty-seven egg proverbs. Some of those egg proverbs are still current, such as "Don't put all your eggs in one basket" and "As sure as eggs be eggs." Others are less familiar, such as "Better an egg in peace than an ox in war," "It is hard to shave an egg," and "Who means to have the egg must endure the cackling of the hen." Other food proverbs survive only by virtue of their being used in Shakespeare, such as "to take eggs for money," meaning "to exchange something valuable for something worthless." Still others have been obsolete for centuries, such as "to come in with five eggs," meaning "to inter-

rupt with an idle story,” while others have been rendered obsolete by changing social conditions, such as inflation: “as dear as two eggs a penny.”

On the other hand, some proverbs persist even when they cease to make literal sense. The proverbial phrase “to bet dollars to doughnuts” is still current even though the rising cost of doughnuts has diminished the original disparity of the wager. Likewise, the proverbial phrase “to eat humble pie,” meaning “to be forced into apologizing in a humiliating manner” remains current even though it has been largely forgotten that “humble pie” was originally “umble pie,” and that the umbles were the innards of a deer, often cooked into a kind of meat pastry. The proverbial phrase “to dine with Duke Humphrey,” meaning “to go hungry,” is still heard occasionally, even though the origin of that expression has been lost even to paremiologists.

Like proverbs in general, many food proverbs have changed their form over time. The early-sixteenth-century proverb “Many things fall between the cup and the mouth” evolved, by the mid-nineteenth century, into the more familiar “There’s many a slip ‘twixt cup and lip.” The use of rhyme in the latter proverb is one of several literary devices that characterize many proverbs, including food proverbs. These literary devices make proverbs easier to remember, and also signify their special ratified status, rather like placing a frame around a picture. Other literary devices include alliteration (as in the fifteenth-century proverb “the more crust, the less crumb”), parallelism (as in the fourteenth-century proverb “the nearer the bone, the sweeter the flesh”), and antimetabole (as in the sixteenth-century proverb “while one wastes drink, the drink wastes him”).

Proverbs, including food proverbs, continue to be invented up to this day, though perhaps not at the rate they were centuries ago. One recent addition, often heard in the more northern parts of the United States and Canada, is the ironic maxim “Don’t eat yellow snow.”

### Food Riddles

While proverbs re-familiarize the familiar, and riddles de-familiarize the familiar, the distinction between the two forms is sometimes unclear. For example, the seventeenth-century proverb “An egg will be in three bellies in twenty-four hours” has the declaratory form of many proverbs, but in substance it is much like a riddle: the three bellies are the belly of the hen that lays it, of the oven that bakes it, and of the human who eats it. Other proverbs can easily be converted into riddles by suppressing, rather than declaring, the familiar element: the sixteenth-century proverb referred to above—“while one wastes drink, the drink wastes him”—becomes a riddle when expressed in this form: “As you waste it, it wastes you.” Aristotle noted that riddles are also closely allied to metaphors: “Metaphors imply riddles, and therefore a good riddle can furnish a good metaphor” (*Rhetoric* book 3, chapter 2). Put another way, many riddles are merely

### MISCELLANEOUS FOOD PROVERBS

Hunger is the best sauce.  
He is an evyll coke that can not lycke  
his owne lyppes.  
Don’t cry over spilt milk.  
The proof of the pudding is in the eating.  
Butter wouldn’t melt in his mouth.

incomplete metaphors: one half of the identity relationship is deliberately elided. For example, this Filipino riddle—“A trunk of a king; if opened it cannot be shut”—becomes a metaphor once the missing element is re-inserted: “An egg is a trunk of a king; if opened it cannot be shut.”

Also like proverbs, riddles are ancient in origin. In the ancient Greek legend of Oedipus, the Sphinx terrorized the people of Thebes when they could not solve its riddle. In the Old Testament, Samson successfully antagonized the Philistines by challenging them to solve this riddle: “Out of the eater came forth meat, and out of the strong came forth sweetness” (Judg. 14:14). The solution to the riddle was a lion, Samson having previously encountered a lion carcass that bees had filled with honey. Ninety-one ancient riddles are also preserved in the Exeter Book, a late-tenth-century manuscript collection of Anglo-Saxon literature. Of these ninety-one riddles, ten are food- or drink-related, including this one, whose bawdy double-entendres de-familiarize the everyday thing implied by the riddle:

I am a wondrous creature: to women a thing of joyful expectation, to close-lying companions serviceable. I harm no city-dweller excepting my slayer alone. My stem is erect and tall—I stand up in bed—and whiskery somewhere down below. Sometimes a countryman’s quite comely daughter will venture, bump-tious girl, to get a grip on me. She assaults my red self and seizes my head and clenches me in a cramped place. She will soon feel the effect of her encounter with me, this curl-locked woman who squeezes me. Her eye will be wet.

The solution to this ribald riddle is “onion.”

Inventing new riddles continues to be a popular activity among some authors and educators. In the nineteenth century Lewis Carroll devised riddles, including a long and elaborate food-related one, for *Through the Looking Glass*. In the twentieth century, J. R. R. Tolkien created many riddles for *The Hobbit*, including this one: “A box without hinges, key, or lid. Yet golden treasure inside is hid.” The solution is familiar: “an egg.”

**PYTHAGORAS.** Pythagoras (c. 580–c. 580 B.C.E.) was a Greek mathematician, philosopher, and mystic. He wrote nothing himself, so his ideas survive through the writings of others, including Aristotle. Many people are familiar with him as the mathematician who formulated the Pythagorean theorem in geometry that relates the lengths of the sides in a right triangle. Others know him as a mystic and the first person known to be motivated by moral and philosophical concerns to adopt a vegetarian diet.

The schools and societies Pythagoras founded in the southern Italian area of Magna Graecia flourished for a while, and they developed and spread many of his concepts, which were later adopted and expanded by others. These concepts include bodily humors (evident in modern descriptions of melancholic and phlegmatic personalities), a tripartite soul, reincarnation, and the numerical

ratios that determine the concordant intervals of the musical scales. Permeating all of his thoughts was the idea that all things are numbers. Numbers (individuals, groups, and series) were imbued with mystical properties that were carefully guarded and only shared among initiates to the Pythagorean schools founded by him or his disciples.

Pythagoras and his followers practiced one of the first recorded diets known as vegetarianism. He advocated a diet devoid of the flesh of slaughtered animals partially because he felt food influenced the distribution of the bodily humors and thereby the health of the individual and partially because it would prevent the killing of a reincarnated individual and its transmigrated soul. Up until the late nineteenth century non-meat eaters were generally known as “Pythagoreans.”

Pythagoras is also alleged to have admonished his disciples to abstain from eating beans. Ancient and medieval writers ingeniously ascribed this pronouncement to the belief that beans contained or transmitted souls. The Greek phrase supporting this gastronomic recommendation, however, could also be construed to imply that his followers should avoid politics. Black and white beans were used as counters in voting in Magna Graecia. The school Pythagoras founded there became actively involved in the populist political views that gained ascendancy in the town of Kroton, where he lived for many years. Later an opposing aristocratic party gained control of the city and banished him and his followers for their political views and activism. Pythagoras died in exile. His supposed warning to “abstain from beans” is therefore thought to have meant “avoid politics.” Alternatively he may have realized that eating undercooked broad (fave) beans (*Vicia faba vulgaris*), a common food of the Mediterranean region, produced a severe hemolytic anemia (favism) in some people. Interestingly the same mutant gene that makes people sensitive to favism also increases their resistance to the malarial parasite, possibly accounting for the widespread presence of the mutant gene in regions with endemic malaria.

**RABELAIS, FRANÇOIS.** Little is known with complete accuracy about the life of Rabelais (1483 or 1494?–1553). Born in or near Chinon, France, where his father was a lawyer, he entered the priesthood as a novice of the Franciscan order. Here he was able to study languages, literature, and the sciences. Abandoning holy orders, Rabelais traveled to Montpellier, where he obtained a degree in medicine and became a physician at Lyons Hospital and a professor of medicine. It is here that he began writing the series of satirical books for which he is best remembered today. The four books (the fifth is of doubtful authenticity) tell the bawdy, rollicking tales of the giants *Gargantua* and *Pantagruel*. Often difficult to read, and frequently misunderstood as works of gross indecency, the stories are strewn with references to eating, food, and drink that help paint a vivid picture of Renaissance life. But it is in the use of food as part of satirical allegory that Rabelais is at his most inspired. Food imagery helps create a cloak of laughter to thinly conceal his pointed comments on important contemporary issues of the day.

One example of the vivid food imagery founds in Rabelais' works occurs in the fourth book of *Gargantua and Pantagruel* when, in the course of an epic voyage, his heroic characters, Pantagruel and the ship's company, go ashore on the Wild Island, ancient abode of the Chitterlings. Here they encounter sausage-people who are locked in an irreconcilable war with their enemy Quaresmeprenant (Shrovetide). Learning that Chitterlings are preparing to ambush the heroes, Friar John orders the construction of a giant sow, similar in principle to the Greeks' Trojan horse, and mans it with a company of noble and valiant cooks ready to do battle in a "culinary

war." In the midst of battle, the cooks spill forth and rout the Chitterlings, handing victory to Pantagruel.

Exemplifying the difficulty people have with the interpretation, this episode has been viewed as either a representation of the battle between Carnival and Lent; as a satire on Church and State, specifically on the German-

François Rabelais, a medical doctor and master of languages, was one of the most learned men of his time. In his exaggerated and irrepressible *Gargantua and Pantagruel*, he attacked the monks' ideal of self-denial with detailed depictions of eating—thousands of cattle must be slaughtered to satisfy the giants' appetites—and of bodily functions. Although he is assumed to have been a great lover of food and drink, as Balzac observed, Rabelais "was a sober man who drank nothing but water." PORTRAIT COURTESY OF THE LIBRARY OF CONGRESS.

"Chitterlings are Chitterlings, always duplicitous and treacherous."

*Book 4, Chapter 36*

speaking Protestants and the Council of Trent; and as a moral message supporting moderation.

Rabelais remains often misunderstood. But his books continue to inspire as literary masterpieces of satire, full of wit and wisdom, and displaying both a genuine humanist love of life and a quest for truth.

**RAMADAN.** Ramadan, the major fast of the Islamic year, falls in the ninth lunar month. Traditionally, Ramadan commences and ends with the sighting of the new moon, though now a standard calendar is more commonly used.

The month-long fast involves abstinence from food, liquids, smoking, and sexual intercourse between the hours of sunrise and sunset, but at night the holiday has turned into a feast in many Arab countries, each of which has its favorite special Ramadan foods and recipes. Moreover, fasting must be undertaken with spiritual intent (*niyyah*), and this intent must be renewed each day before dawn. Mean-spirited words, and thoughts and deeds

such as slander, lying, and covetousness negate the value of fasting. The fast commences each day at dawn, immediately prior to which an early morning meal, *subhoor*, should be eaten. It usually includes a special bread called *mushtab* and a sweet cream-filled pastry called *kilaj*, which are served only during Ramadan. During the day no food or drink may be taken, which can be a severe test when Ramadan falls during the hot summer season. The day's fast is broken with a small meal, *iftar*, taken as soon as possible after sunset. Traditionally, this is dates and water in remembrance of Muhammed, who always broke his fast by first eating dates, followed by lentil soup and salad. A larger, often quite elaborate meal may be eaten later at a mosque or shared with visiting friends and family. There are no particular rules governing what should be served for the main course. Sweets are very popular during Ramadan.

Although the fast is obligatory for all sane adult Muslims in good health, a number of exemptions are allowed. These are seen as proof of Allah's wish not to place too onerous a burden on His people.

1. Children are not required to fast until they reach the Age of Responsibility (twelve years for girls; fifteen years for boys). Children from the ages of six to eight may fast for half the day, gradually increasing the duration until old enough to fully observe the fast.
2. The elderly and the chronically ill whose health may be compromised by fasting may substitute the feeding of one poor person for each day of fasting missed.
3. Pregnant and nursing women, women in post-child-birth confinement, and menstruating women may postpone the fast and make up the days later.
4. Those who are sick, traveling, or engaged in hard labor may make up missed fast days later.

Unintentional breaking of the fast is not punished, and Muslims are enjoined to break their fast if there is a threat to health. Other types of infractions require restitution. This is of two kinds: *Qada*, which involves making up missed days, and *Kaffarah*, which additionally exacts a penalty from the transgressor.

Fasting in a religious context is often undertaken for reasons of self-denial, penance, or mourning. In contrast, the Ramadan fast is a festive occasion of gratitude and thanksgiving to God. It has also acquired moral, social, and physical virtues. Observance of the fast is commonly seen as a way of receiving pardon for past sins; it creates empathy with the plight of the hungry, and it teaches self-control and endurance of deprivation.

Following Ramadan there is a three-day festival of prayer and feasting known as 'Al Id-Fitr. Special sweet dishes are prepared, giving the festival its other name of Sweet Id. Muslims give thanks to Allah for enabling them to perform their duty of fasting, and there is much visiting and exchange of gifts, including food, with family and friends. Charitable giving is also encouraged.

**RATIONING.** Food rationing is a program by which governments or private organizations oversee the allotment of food to citizens, usually during times of war or scarcity. By ensuring that all people get enough to eat or at least have a chance to purchase highly desired foods, mandatory rationing of food helps maintain citizens' physical health and psychic well-being. In doing so, it helps secure public allegiance and compliance, factors critical to institutional welfare during wartime or in the midst of a food crisis. In addition to ensuring an equitable distribution of scarce resources, rationing accompanied by price controls is designed to combat fierce inflation that often occurs with heightened demand and inadequate supply. Items distributed through such systems are often referred to as rations. Goods bought and sold illicitly outside of rationing and price control programs are said to be on the black market. Rationing is arguably a more democratic system of distributing food and other scarce resources. Theoretically, its most distinct function may be that of leveling economic and class inequality. Those on the lower end of the economic spectrum, for example, and those without the luxury of time to wait in long lines or to scout out caches of available goods, are allowed an equal chance to purchase high-status foods.

Rationing has also been used for more complicated or nefarious reasons. At one point, food allowances given to indigenous peoples in Australia and the United States, among other places, functioned as a form of social control. For Australian Aborigines, food rations were used as a tool to draw people to certain areas; their removal was intended as a form of punishment. Adolf Hitler, convinced that the German public had turned against the Weimar Republic because of food shortages, employed rationing in the 1930s to avoid domestic food emergencies. Occasionally, rationing has been implemented to ensure the unequal distribution of food, as when World War II concentration camp inmates voluntarily rationed food according to age and physical state (in the hope that this would allow the most able-bodied to survive). In early-twentieth-century China, rationing was controlled by elite "team leaders" who were allowed to distribute food and other goods according to personal discretion,

Food rationing often occurs during times of national crisis, as in England during World War II. These English housewives are queuing up at a meat shop that sells horse meat which is, according to the sign near the door, "Passed as Fit for Human Consumption." © AP/WIDE WORLD PHOTOS.

which in turn afforded them power and control over local peasants. Most often, however, rationing has been employed to allow a relatively equal dispersal of food among citizens (with some reduction in allotment to infants and young children, and occasionally the very elderly). In Great Britain, World War II rationing is credited with improving the health of many by allowing the economically disadvantaged access to a stable, nutritious food supply. Currently, food rationing is most frequently implemented in countries that are the targets of international sanctions, including Cuba and Iraq.

Food rationing has been practiced in virtually every society of record, from antiquity to the present, in countries all over the globe, including Argentina, Australia, Bangladesh, Canada, Chile, China, Cuba, France, Germany, Great Britain, India, Iran, Iraq, Israel, Japan, Mexico, the Netherlands, Pakistan, Russia, and the United States. Rationing was practically universal during World War II, and continued for several years afterward in many parts of the world, including industrialized countries, which traditionally have had a more stable food supply than developing countries, whose governments have tended to implement food rationing more frequently out of necessity.

Foods deemed critical to ration can be either staples or luxuries. Staple foods—those vital to basic survival and the central elements in a cuisine—often vary according to culture, region, and tradition, and may include rice, flour, bread, milk, meat, cooking oil, canned goods, and salt. Highly desirable, psychologically important items such as cheese, butter, sugar, coffee, tea, and tobacco are arguably as important as staples to ensuring public contentment and cooperation, and thus are regarded as essential to ration. Such nonfood items as shoes, clothing,

gasoline, heating oil, and tires are typically rationed in times of scarcity as well.

Food rationing tends to be implemented through two methods, the coupon system or the point system. During World War II, for example, sugar and coffee were rationed in the United States according to the coupon method, under which consumers would relinquish a coupon to purchase an allotted amount every few weeks. For rationing meat, butter, and canned goods, the government introduced the more complicated point system. Each month the federal Office of Price Administration (OPA) issued each person five blue and six red stamps worth ten points each, a total of fifty blue points for processed foods and sixty red points for meat, fats, and some dairy products. Each item—canned pineapple or pork chops, for instance—was assigned a point value determined by both availability and consumer demand. The point values were periodically reevaluated; for instance, the OPA lowered the point value of canned peaches to encourage increased consumption following a 1943 bumper crop of the fruit. The point system maintained government control over rationing but at the same time allowed the consumer a reasonable amount of control over the family's diet. With such a system, a consumer could choose to spend some of the family's points on more highly desired and scarcer items with high point values, such as beefsteak, knowing that fewer points would be left that month to buy other meats and fats. The system had its flaws, but consumers in general consistently supported it, and some even campaigned to continue rationing through the postwar years in order to allow more food to be distributed to war-ravaged and famine-stricken countries overseas.

The success of rationing in any country is highly dependent on efficient and effective administration and on unyielding honesty of and cooperation among government officials, farmers and food processors, wholesalers, grocers, and consumers. Rationing can break down at any level and through a variety of means: theft of ration books and favoritism in their distribution; lowering or misrepresenting the quality of products produced (shrinking the size of bread loaves; adding inferior grain); selling goods for higher prices or without collecting ration points; hoarding food; or bribery. While rationing has been deemed ineffective in many places, as in the Soviet Union during its early period, it is remarkable that, given its potential to break down at any point, the system has succeeded so much of the time. For the city of Lyons, France, in the Great Winter of 1709, food rationing along with other forms of public relief successfully averted widespread famine. Israel in its early years of statehood relied heavily on rationing to equitably apportion meager supplies of food.

### Politics of Rationing

Because voluntary compliance is crucial to the success of rationing, concerted propaganda campaigns, even in

openly democratic countries, are designed to urge people to feel personally invested in complying with rationing. Food is politicized, whether consumed in public or in private spaces. With wartime rationing, the grocery store, the kitchen, and the family meal—where food is purchased, prepared, and consumed—become public spheres as rhetorically important as the battlefield. Farmers with pitchforks and gardeners with trowels are likened to soldiers bearing rifles. Women, as traditional food procurers and preparers, become akin to soldiers at the battlefield. Wasting or hoarding food is characterized as aiding the enemy. Sacrificing food in order to send more to the military, or growing one's own food so that commercially prepared food is more available to distribute to citizens under enemy rule, is seen as performing one's patriotic duty.

Food rationing can become a positive site for communal expression of democratic obligation. Preventing waste, avoiding black markets, producing food, and abiding by rationing, however trivial they may have seemed, allowed American citizens during World War II to contribute to, and feel a part of, the war effort daily and communally. By sacrificing some of their abundant food supply to send more to the military and to those in desperate need, people could exhibit their patriotism and support of the war. Rationing not only ensured a sufficient, if at times unexciting, diet but also helped instill a sense of public commitment to the war, community involvement, and patriotism. These same sentiments have prevailed in other countries and times as well.

Despite its potential for positive meanings and uses, the implementation and eventual dismantling of rationing can be highly political. Food producers and processors may exert extreme pressure to lift rationing, arguing that consumer demand for goods should be unfettered. Those opposed to centralized food distribution see rationing as placing too much power in hands of government. Government officials benefiting from the program in any number of ways may be reluctant to disassemble the system. While some consumers have regarded food rationing as too restrictive and anticapitalistic, most, in times of crisis, have considered it as the (albeit imperfect) guarantor of their entitlement to a stable food supply.

**RECIPE.** A recipe is a set of instructions or advice for preparing food. The English word comes from the Latin imperative *recipe* for "take," because recipes typically used to start, "Take one pound of flour. . . ."

The modern recipe often follows this format: (1) a title or a brief announcement of what is to be achieved; (2) a list of necessary food ingredients and sometimes special equipment; (3) the method, which spells out the steps to achieve the finished dish or component; and (4) serving instructions. A recipe can also include explanatory notes, which might give advice about ingredients, including possible substitutions; tips on method; snippets of historical and cultural background; and an acknowledgment of the source of the recipe. Particularly in collections, a recipe might come with comparative data, such as difficulty rating, total time necessary, and likely cost of ingredients.

An effective recipe requires maximum accuracy, minimum ambiguity, and an appropriate level of detail for its audience. Omitting one step or ingredient can be catastrophic, and imprecision can leave the cook frustrated. Barbara Gibbs Ostmann and Jane L. Baker help authors, particularly Americans, in *The Recipe Writer's Handbook* (2001).

The form of a recipe has been broadly consistent for thousands of years, although older recipes usually provide less detail because cooks had command of the techniques, which tended to be less demanding. The ancient Greek cookery writer Philoxenus of Leucas wrote, "For [seafoods] the casserole is not bad, though I think the frying-pan better." Elsewhere he advised, "The wriggling polyp, if it be rather large, is much better boiled than baked, if you beat it until it is tender" (Athenaeus, vol. 1, 1927, pp. 21, 23). If these are typical, they help explain why the vast gastronomic compilation *The Deipnosophists* (Philosophers of dinner) made by Athenaeus about 1,800 years ago includes so few recognizable recipes. Philoxenus's advice presumably helped with novel foods in the flourishing Greek marketplace.

Another common purpose for a recipe is as an aide-mémoire (memory prompt) for occasional or complicated procedures, and a cook's shorthand can be difficult for others to decipher. A recipe can be prescriptive, particularly in religious and medical uses. It can provide an

ethnographic record, and gourmets have brought notes back from their travels since ancient times. A recipe can play an important part in culinary reproduction, as when a delighted guest takes home a copy. It might be a teaching device, as in the great compilations of household management. It might promote a chef, restaurant, cooking school, or commercial product, such as a proprietary ingredient or a generic food like beef. A recipe can even become literature in its own right and be read for pleasure.

While a recipe is a powerful aid, it never replaces actual experience. Without some knowledge, the maker of a *beurre blanc* sauce could never be confident of having succeeded. No two cooks ever produce identical results from the same recipe. Julia Child and her colleagues Simone Beck and Louisette Bertholle required lengthy detail to introduce solid technique to many Americans with *Mastering the Art of French Cooking* in 1961. While recipes seem to promise the whole world of cooking, there is pressure to rely on a standard repertoire of techniques. Successful recipe writers are advised to restrict themselves to readily available ingredients. Recipe-based cooking favors smart-seeming compositions over untouched foods, however excellent.

### An Ancient Invention

Written recipes are presumably as old as literacy, which emerged to control food supplies in the earliest civilizations. Recorded instructions had the advantages of wide and accurate transmission and archival retrieval. The power of naming, discussing, and borrowing was reserved to the tiny literate elite for thousands of years, contributing to the separation of high cooking, investigated by the social anthropologist Jack Goody in *Cooking, Cuisine, and Class* (1982). In general, traditional societies did without recipes in the sense of formal accounts, usually written, of food preparation. A girl watched and helped her mother with familiar routines, and an apprentice was shown trade secrets.

The oldest surviving recipes are probably those impressed into three clay tablets 3,700 years ago somewhere in what is now Iraq. Held in the Yale University cuneiform collection and previously mistaken for pharmaceutical formulas, the recipes would have been recorded by Babylonian scribes on behalf of the male cooks of a temple or palace. Their translator, Jean Bottero, said the best-preserved tablet fits twenty-five recipes into just seventy-five lines. The recipes list the chief ingredients, the basic steps, and the name, which is derived from the chief ingredient or appearance when served. The only other readable tablet devotes 250 lines to seven recipes for various kinds of birds, both domestic and game. The recipes indicate many steps, numerous utensils, and complex combinations.

Some of the earliest Chinese recipes, at least 2,500 years old, are contained in the sprawling text *Li Chi*, which originated in the Chou dynasty. Reprinted by K. C. Chang in a chapter in *Food in Chinese Culture* (1977),

## HOW TO READ AN OLD (HANDWRITTEN) RECIPE

Old manuscript recipes are frequently difficult to interpret because they were often written as personal memory aids for the cooks, and for their eyes only. Added to this is the difficulty of archaic language and the fact that writers spelled words as they pronounced them, as in the case of the following recipes from the cookbook of Francis Boothby, dated 1660. (Francis was either the wife or daughter of Sir Thomas Boothby of Essex, England.) Her recipes can be adjusted to modern English in the following manner.

### 33. Sace [Sauce] for a Shoulder of Mutton

A few oysters, some sweet herbs, an onion, a pint of white wine, a little beaten [ground] nutmeg, and large [whole] mace. A lemon peel [grated zest]. If you have no oysters, a few capers instead, and the gravy of the mutton.

[The oysters were pickled in brine, which is why capers can be substituted.]

### 34. A White Pote [A White Pot: Baked Custard]

Take a pint and a half of cream, a quarter of a pound of sugar, a little rosewater, a few dates slit, some reasons [raisins] of the sun, 6 or 7 eggs, large mace [whole mace], a slice of pippin [tart cooking apple] or lemon, sippets wet in sack [slices of toast softened in white wine]. Put them in your dish. So bake it.

### 35. Sace [Sauce] for a Pickerell [pickerel is a fish]

Take some claret wine [any red Bordeaux wine], thicken it with grated bread. [Add] a sprig of rosemary, a little beaten [ground] cloves, and synamon [cinnamon], some sugar, [then] set it on the fire, let it boile a little [boil up until it thickens]. So serve it.

William Woys Weaver

they instruct: "For the (Soup) Balls, they took equal quantities of beef, mutton and pork, and cut them small. Then they took grains of rice, which they mixed with the finely cut meat, two parts of rice to one of meat, and formed cakes or balls, which they fried" (Chang, 1977, pp. 51–52).

Europe's oldest recipe collections were written at the end of the fifth century B.C.E. by Greeks in southern Italy, and the first of these was probably *The Art of Cookery* by Mithaikos of Syracuse. Athenaeus has handed down only one recognizable recipe, which says, "Clean the insides of a ribbon-fish after cutting off the head, wash and cut into slices, and pour cheese and oil over them" (Athenaeus, vol. 3, 1929, p. 465).

The oldest surviving collection in the West is the *De re coquinaria* (Art of cooking), which was attributed to a Roman gourmet called Apicius and was compiled around the year 400 C.E. More of than half of the nearly five hundred entries are devoted to the preparation of sauces. Recipes flourished during other periods of gastronomic ferment, such as the Arab culinary excitement after the advent of the Abbasid dynasty in the eighth century and Chinese cookery with the Sung period from the tenth century.

In medieval English manuscripts, numerous sentences begin "Tak wyte wyn" (Take white wine) and "Tak partrichys rosyd" (Take roasted partridges). Others instruct "Nym water" and "Nym swete mylk," using the archaic "nim" (or "nym"), which means "take." Yet others start "Recipe brede gratyd, & eggis" (Take grated bread and eggs), borrowing the Latin verb *recipere* (to take). Medieval recipes generally did not include measurements and times, providing a challenge for modern interpreters, who often are divided over how spicy the original dishes tasted.

The proliferation of recipes in Europe was boosted by the advent of the printing press (using the principle

A page from the manuscript cookery book of Frances Boothby, dated 1660. Frances Boothby was either the wife or the daughter of Sir Thomas Boothby of County Essex, England. ROUGHWOOD COLLECTION.

## HOW TO WRITE A RECIPE

The elements of effective recipe writing vary according to the recipe's intended purpose and audience. For example, a personal reminder by a working cook will be very different from a travel writer's evocation of the flavor of an exotic dish. Yet some requirements are relatively constant, including the need for accuracy, completeness, and lack of ambiguity. Like a rotten apple, just one missing ingredient, mistaken measurement, or misleading instruction can spoil the whole recipe, and one faulty recipe can spoil a whole collection. Seeking to maintain a reputation for reliability, many publishers provide authors and editors with recipe style guides, and expect recipes to be tested in test kitchens.

Food businesses and industry associations that use recipes for marketing purposes also go to great lengths to ensure that the writing is effective. Such marketers want newspaper cookery writers and others to relay the recipes, which they will do more readily if they have confidence in the source.

The (U.S.) National Cattlemen's Beef Association keeps its recipe style guide up-to-date, and revised it in accordance with the the results of research (Gatten & Company, Chicago, 1992) regarding consumer preferences in recipe formats. This study found that consumers primarily desired "ease of preparation." Recipes should not merely "eliminate guesswork," but also appear easy, something accomplished by a simple format and style.

Based on this research, the recipe style guide of the Beef Association's test kitchens includes these recommendations:

- Use a straightforward descriptive name for the finished dish, rather than a name that is fun or creative.
- Indicate preparation and cooking times at the beginning.
- List ingredients separately at the top of the recipe.
- List the main ingredient (such as meat) first.
- Group other ingredients according to the part of the recipe for which they are needed.
- Choose readily available ingredients or substitutions.
- Try to give more than one measure for each ingredient, for example, "4 cups cooked shell macaroni (8 ounces, uncooked)."
- Avoid abbreviated measures, for example, "teaspoon" rather than "tsp."
- Specify the equipment and utensils when possible.
- List the preparation steps with numbers or bullet-points, since this makes the recipe look simpler.
- Do not "divide" an ingredient (for example, "mix half the flour"); provide a precise measurement for each use.
- Do not write "one teaspoon each of sugar, cinnamon, and nutmeg"; repeat the measurements for each ingredient.
- Provide preheating directions.
- Make the recipe easier to read by using large print.
- Provide a photograph of the finished dish.

*Michael Symons*

of grape and oil presses) around 1440. The relatively ready availability of recipes facilitated social emulation and gastronomic discussion and broke the nexus of master-apprentice. Early modern cooks may have been reticent to publish arcane information, but the dearth of French publication ended in the 1650s. As Barbara Ketcham Wheaton suggests in *Savoring the Past* (1983), "Perhaps the balance shifted, and secrecy became less valuable than fame" (Wheaton, 1983, p. 113).

Several modern features were established around the middle of the nineteenth century. Until then the more usual English word was "receipt," from the feminine past participle of the same Latin verb, *recipere*. "Recipe" had predominantly been used for medical prescriptions (leading to the abbreviation R or Rx), with which culinary prescriptions had overlapped. It has been suggested that "recipe" eventually won out because it appeared more learnedly Latin.

In the early 1800s the title was often still of the descriptive form, announcing what would be achieved; for example, Priscilla Hazehurst explains in the *Family Friend* (c. 1810), how "To make a Bride Cake" (p. 76), "To preserve Damsons another way" (p. 107), "To disguise a Leg of Veal" (p. 147), "To boil Artichokes" (p. 161). The concern was to treat individual foods properly rather than to transform them into a higher order of creation, that is, into named "dishes" (or "made dishes," as they were called).

The most important change early in the nineteenth century was toward numerical rigidity. Instructions such as "do it till it is done" can be unsettling. However, traditional cooks knew when "it is done" better than they knew "twenty-five minutes." Abstract time measurement and punctuality only became ingrained in industrial, urban society. The preoccupation with precise recipes belongs to "rationalization," the shift from hands-on,

This plate from Jules Gouffé's *Royal Cookery Book* (London, 1868) shows the proper method for cutting up a chicken into serving-size pieces. This is an example of how a written recipe could never convey in words the carving process that is obvious at a glance from the picture. ROUGH-WOOD COLLECTION.

traditional methods to calculation, measurement, and control.

In 1817 the English author William Kitchiner claimed that his book *Apicius Redivivus; or, The Cook's Oracle* introduced scientific precision. Writing for the "rational Epicure" (Kitchiner, 1821, p. xi), he rejected obscure expressions like "a little bit of this—a handful of that." His recipes were the "results of experiments carefully made, and accurately and circumstantially related" (Kitchiner, 1821, pp. 30–31). The time requisite for dressing was stated and the quantities set down in number, weight, and measure. "This precision has never before been attempted in Cookery books," he boasted, not entirely accurately (Kitchiner, 1821, p. 31). Even then, an English cookery book did not require many measurements. The bulk of Kitchiner's recipes explained each of the main methods, which for him were boiling, baking, roasting, deep frying, and broiling. The few recipes for accompanying sauces specified quantities. The category of "Broths, gravies, and soups" also occasioned some pre-

cision. This left merely the final one-eighth of the book to cover expressly "Made Dishes, &c.," prescribing the likes of Haricot of Beef, Broiled Rump Steak with Onion Gravy, and Bread and Butter Pudding. As many cooks can confirm, recipe measurements have remained imprecise and inconsistent. American writers tend to use volume rather than weight, so measures of even sugar and flour are given in "cups." "Teaspoon" and "tablespoon" are hangovers from a less-finicky era. Many recipes contain vague statements such as "low heat."

With mass literacy and the mass production of cookery books from the mid-nineteenth century, enormous treatises extended to a thousand pages and by the early twentieth century exceeded two thousand pages. Meanwhile cooks exchanged innumerable recipes on scraps of paper and in exercise books.

Since the late nineteenth century, recipes have been a widespread marketing device, intruding into domestic culture on behalf of new products from gelatine to elec-

tric stoves. Incalculable numbers of recipes arrive on packaging; supermarket leaflets; in newspapers, magazines, and books; and on the Internet. Customers are invited to “send a self-addressed envelope for a free copy of our recipe booklet.” With much at stake, food manufacturers and marketing bodies rely on highly experienced writers and “test kitchens” to generate promotional recipes that are readily understood and immediately successful. In turn, many cookery writers in newspapers and elsewhere rely on these recipes.

### Recipes as History

Old recipes provide clues as to how others dined, but their relationship with actual practices is far from straightforward. The existence of a recipe might even be misleading, because the need for an aide-mémoire suggests rarity; common procedures did not need spelling out. Printed texts have often represented a sometimes idiosyncratic or idealized version of reality. For such reasons, culinary historians have shown an interest in personal recipe manuscripts. Relatively little concerted effort has yet gone into recording actual foodways before they are lost, however.

As recipes shifted in identification from seemingly ageless traditions to individual creativity, plagiarism became an issue. Eighteenth-century authors commonly protested their own originality against others' piracy. Reviewing his predecessors, Kitchiner declared that “cutting and pasting seem to have been much oftener employed than the Pen and Ink” (Kitchiner, 1821, p. 24). Eliza Acton was honest enough to boast in *Modern Cookery* in the mid-nineteenth century that she relayed “carefully tested recipes,” and she appended the occasional notation “Author's Receipt” and “Author's Original Receipt” rather than see “strangers coolly taking the credit and the profits of my toil” (Acton, 1868, p. ix).

Contributors to the cookery history journal *Petits propos culinaires* have meticulously tracked down and exposed particular eighteenth-century plagiarists, such as Vincent La Chapelle, who stole from François Massialot's *Le [nouveau] C[uisinier] royal [royal] et bourgeois* (1691); Hannah Glasse, who purloined extensively; and John Farley, who lifted from Glasse and Elizabeth Raffald. Yet meticulous sleuthing, such as Fiona Lucraft's in “The London Art of Plagiarism” on Farley “the fraudster,” can be seen as a misplaced preoccupation with property rights in an unashamedly collective form, in which everyone borrows from everyone. A recipe might almost be the better for not being original, for having proved itself. In the converse of plagiarism, cookery authors acknowledge a source and then provide a “modernized, adapted” travesty.

Recipes remain essentially in the public domain. Belonging to no one, they are free and innocent. Or they would be, except for recipes as commercial promotions, which are quickly joining the scarcely traceable pool.

Michael Symons

**RELIGION AND FOOD.** There are almost as many ways to define religion as there are religions, but scholars basically tend to think about it in two ways. Some concentrate on religion's functions in societies while others focus on grasping its mysterious, universal essence. This essay will examine how food factors into these ways of understanding religion. The connections between religion and food vary widely and are often quite complex. There are, however, several common connections between religion and food that scholars have begun to document in recent decades.

### Function

In the functionalist view, religion provides meaning, identity, and structure within what Geertz has called “cultural systems.” Religion reflects the human desire for

order, but it provides order because people believe it has its origins in the divine. Food often figures prominently in functional interpretations of religion. Lévi-Strauss described food as a type of language that helps human beings express their basic perceptions of reality. He observed that rules about eating cooked and raw foods in some cultures are dictated by sacred stories (myths) and prohibitions (taboos). These rules reflect underlying notions about differences between nature and culture.

Mary Douglas has shown how food communicates ideas about holiness that provide identity and order. The ancient Hebrew dietary laws functioned as controls on identity in a context in which incursion by other tribes and their gods was a frightening possibility. To be holy, in this context, is to be wholly separate. Israelites were “clean” because they remained within the bounds of God’s covenantal order, not mixing with outsiders, their gods, or their ways. This separation was reinforced by dietary restrictions such as the prohibition against eating pork. Pigs are “dirty” because their physical characteristics are abnormal according to the way in which the ancient Israelites understood types of animals (i.e., they have cleft hooves and do not ruminate, unlike the edible animals otherwise similar to them like cattle and sheep). A pure and separate people does not make an animal that is not clearly like other grazing animals part of itself by consuming it. Purity of food and body help to strengthen the boundaries of Israelite society and religion. The laws of kashruth have continued to be among the distinguishing marks of Jewish identity and lifestyle through the centuries.

Functionalist understandings are especially helpful for exploring the relationships between religion and food in particular contexts like ancient Israel. They also illuminate the connections between religion, food, and other culturally constructed systems such as gender norms. Scholars have shown how Graeco-Roman table etiquette affected the development of women’s roles in early Christianity and may help to explain the tension around women’s leadership in early Christianity (Corley). Focusing on gender and food expands our understandings of the scope of religion. Feminist scholars have shown that women may be religious experts through their control of food in societies where previous scholarship has focused on the male exclusivity of sacred knowledge. Among the Thai Buddhists that Van Esterik studied, it is the women whose feeding of monks and deities primarily determines attainment of merit and thus shapes the eternal destiny of their people both dead and living. Bynum’s study of medieval Christian mysticism shows that women exercised control and spiritual power through refusing to eat or eating only in a spiritual manner.

Religious food rules may also be codes for class distinctions. The Hindu caste system, for example, is communicated primarily in terms of who can cook for and who can eat with whom. Religious purity is attached to the maintenance of social boundaries. Brahmins, the

highest caste, maintain their purity by avoiding foods touched by those of lower castes. Yet Brahman-prepared food is permitted to all. In ancient sacred myth, Brahman created the world by cooking it in sacrifice, thus performing a priestly act. A Brahman’s privileged status in society still is enforced by his role as priest. He stands between the gods and rest of the world. As the ancient texts declare, the world cooked by the Brahman is to fulfill its duties to him (Malamoud).

### Essence

Here, religion primarily refers to the human encounter with an irreducible sacred such as a god. Scholars such as Mircea Eliade map this experience through universally recognizable types of orientation (sacred time and sacred space), narrative (myth), and activity (ritual). Religion in this view essentially concerns the otherworldly expressed and responded to through patterns, which often involve food.

Those patterns are still important for describing and understanding religion, even if their universality has been questioned. As Jonathan Z. Smith puts it, they serve the observer as “maps,” but should not be confused with the vast diversity of “territories” known to believers. They are more like recipes written by a food professional based on traditional dishes that community cooks make from scratch by heart. Sacred time, sacred space, ritual, and myth as categories only give the general flavor of a religion.

**Sacred space and time.** Sacred space often focuses on food and table setting. The most holy point of some Christian churches is the altar where the sacred meal of Christ’s body takes place. In others, a pulpit might replace the altar; however, it is from that point that Christians are fed God’s word. In Hindu temples, devotees are often separated from images of the deities by a rail from which they offer food to the gods and receive it in turn. Sacred space is the place where the divine and human communicate, very often over a meal.

Domestic eating spaces can be sacralized as well. Hindu and Buddhist homes may have shrines that are miniature temples for deities who are fed daily. Chinese kitchens contain a shrine to the stove god. In Sicily and Sicilian communities in the United States, families construct elaborate altars of food to celebrate St. Joseph’s Day. During *Sukkoth*, tent-like dwellings outside their homes remind Jews of their nomadic ancestors as they celebrate the harvest’s bounty.

Sacred time is also often delineated by food. In many religions, time is marked by periods of eating and abstinence. Fasting during Ramadan is one of the five pillars of Islam, and the cycle of eating and abstaining from food marks its days. These are holy times, where one’s relationship to food expresses one’s connection to holiness through a balance of disciplined avoidance of carnal pleasures and partaking in Allah’s bounty. Both feasting

and fasting, in different ways, are concerned with submission to Allah.

**Ritual, myth, and symbol.** Eating in sacred space and at sacred times is a primary mode of ritual activity. Ritual unites believers with the holy as they carry out patterned activities that parallel those of gods or ancestors. The Passover meal commemorates and reconnects Jews with the ancient Israelite ancestors through the bitter herbs, the sacrificed lamb, and the quickly made unleavened bread. “You shall observe this rite as an ordinance for you and for your sons forever,” Exodus 12 admonishes the Israelites about this practice. “Do this in remembrance of me” is evoked each time Christians reenact Christ’s last supper with his disciples. By commemorating Christ’s last meal, repeating his words and gestures, Christians re-create the sacred time of Christ and his disciples and eat with him again as they eat in community as his body. Or, Christians believe that they actually eat Christ’s sacrificed body in the form of the bread host and in so doing are incorporated into it “to live forever” with God. It is first of all feeding the deity, rather than feeding on the deity, that sanctifies Hindus who present foods to the gods for their consumption. The gods then return the leftovers as sacred *prasadam* for devotees to eat.

Sacred boundaries of time and space and ritual activities are narrated in sacred stories or myths. For the believer, mythic truth is truer than fact; it is the way the gods did it. In the Christian Eucharist, the priest begins with the words of sacred myth: “. . . the Lord Jesus the same night in which he was betrayed took bread: And when he had given thanks, he brake it, and said, Take, eat: this is my body, which is broken for you: this do in remembrance of me.” (1 Corinthians 11) Following the mythic pattern correctly in ritual is of utmost importance since it is a recreation of cosmic order; however, religious communities often disagree about details of performance as well as interpretation. Rituals generally represent beginnings that come out of chaos or involve a change of state. Food, as something that changes state or that can create new identity in communal consumption, is often the centerpiece of ritual controversy. A familiar example is the debate over the real or symbolic presence of Christ in the Eucharist that became the most divisive theological issue of the Christian reformations of the sixteenth century.

The preparation and consumption of food are common in myth. As in the Hindu scriptures already discussed, creation and food are often related in myths of origins. In the Abrahamic religions (Judaism, Christianity, and Islam), the origin of sin takes place in a forbidden act of eating. And it is eating the sacrifice of the Passover lamb or “Christ, Lamb of God,” that restores their relationship with God for Jews and Christians respectively. For Muslims, God rescues their progenitor Ishmael from thirst by a miraculous spring in the desert. Muslims fulfilling the hajj reenact Hagar and Ishmael’s

Food plays a significant ritual role in all of the world’s religions as well as in the religions of the past. This bronze Celtic bucket discovered near Aylesford, England, was used to hold the ashes of a cremated noble. Around it were placed various foods the deceased was to partake of in the afterworld. The bucket is in the collection of the British Museum, London. © WERNER FORMAN/CORBIS.

quest for water as part of the pilgrimage into sacred time and space.

When myths no longer function to order human activity, when they cease to speak of the holy, they are myths in the more common sense of the term. Myths are, however, quite resilient, especially ones involving food. An underground Christian sect in Japan that survived the suppression of Christianity in the seventeenth century accommodated its situation by celebrating sacred meals with fish and rice wine rather than unavailable bread and wine (Whelan). When the buffalo were erased from the North American landscape, the Oglala Sioux accommodated by treating the cattle forced on them by the United States government as if they were buffalo, hunting them ritualistically. This not only preserved their myths, ritual hunts, and feasts, but also quickly changed their dietary preferences. Whereas they had previously avoided beef as unsavory, it quickly became an accepted food staple (Powers and Powers).

Japanese Christians and the Oglala were able to adapt and survive through shifts of symbolism. Symbols are the building blocks of myth. Food symbols are among

the most powerful because they connect the reality of life in a place to the holy in tangible and vital ways. Ghee, clarified butter from the sacred cow, feeds deities and humans in India. Survival in Japan depended on rice and rice was already sacred in indigenous religious traditions there. The Christian minority initially took bread and wine as identity markers that differentiated it from the dominant culture; but when survival was threatened, they christianized an older symbol, rice wine. While food seems to be a universal sacred symbol, meanings can vary broadly. The cow so sacred to Hindus that it must not be killed, is the “spotted buffalo” sacralized in its killing and consumption by the Oglala.

Symbols are also powerful because they communicate the holy through what they are. Wine and bread remind believers of Christ’s blood and flesh by their physical properties. Christianity has debated whether the Eucharistic meal is a perpetual sacrifice, is like a sacrifice, or recalls a final sacrifice. Some early Christian vegetarians interpreted Christ’s death as the end of all sacrifice, including the slaying of animals for human consumption. They marked their sacred meals with water, rather than the blood-like wine. Medieval theology, however, reinforced the sacrificial understanding of the Eucharist; a bleeding host was a common element in medieval devotional stories told to emphasize the sacrifice of Christ’s flesh in every ritual meal performance.

Some scholars hold that sacrifice, which literally means “to make holy,” is at the root of religion. Much mythic vocabulary associates death and food in the service of life. Many religious groups deal with the death-giving-life paradox by sanctioning killing as a gift to the gods, of which humans may share and become holy themselves. Others, like the Jain of India, deal with the reality of suffering by trying to avoid it. For them, eating from plants not killed in the process of harvest and totally avoiding meat are major forms of achieving a meritorious existence. Buddhist monks avoid getting mired down in the world of suffering by refusing to kill animals for food. They may, however, eat whatever is provided for them by householders as long as they remain detached from the desire for it.

Sacred rituals reintegrate believers with each other as well as the gods; this is often accomplished in commensality. Eating the same foods, often from common vessels, draws boundaries around community, making it holy and like family. Early Christians adapted the kin-based Jewish Passover to bond spiritual brothers and sisters. Food exchanges or ceremonial meals are common in marriage rituals. The ancient Jewish wedding was essentially a meal that brought together husband, wife, and their kin. Hindu marriages still involve elaborate exchanges of food. Extension of the community through eating is not always a hospitable occasion. Again, death is often involved in a shared sacrifice. For the ancient Aztecs, eating from the bodies of human victims was a

way of incorporating their strength as well as feeding with the gods (Carrasco).

Rituals often extend outside the bounds of community through food. The Christian Eucharist concludes by sending believers who have been fed “into the world in peace” to help sanctify it. Making the world holy is often accomplished by the extension of community through charitable feeding. Devotees of Lord Krishna, for example, are famous for their temple feeding programs. By feeding the outsider, they serve Krishna by extending his presence through food that has been sanctified by him (Singer). Muslims are required to practice charity and often do so by giving food to non-Muslims. *Bakra Eid* commemorates the sacrifice of Ishmael and is a day on which Muslims worldwide bind community through sacrificing at the same time. But the community is extended in this event, in which sacrificed meat may be portioned out not only among family and the poor, but also to non-Muslim neighbors (Murphy).

### **Food, Religious Performance, and the Body**

Religious peoples are more likely than scholars to appeal to essential experiences of holiness when they articulate religious foodways. That is, when they consciously articulate them at all. Helpful here is the work of Katherine Bell and Ronald Grimes, who emphasize the performative character of religious behavior. This is particularly important for understanding the relationships between religion and food. Most people harvest, kill, eat, cook, serve, hunger for, or otherwise encounter food and holiness primarily through physical action and sensation, rather than through belief and interpretation. The power of foods to evoke strong memories and feelings, essential to the efficacy of religious ritual, is related to the sensory experience of food. Food rituals recall not just abstract ideas, but smells or tastes that bring back another time or place. Passover offers Jews the opportunity to reconnect viscerally with their ancestors through tastes of what their lives were like on the Seder plate.

It is important to underline this embodied nature of the connection between religion and food. Because religious experience via food is a physical experience, it can vary widely even while following the same ritual practices. This does not make ritual less powerful; rather, it helps to bring it alive for devotees. Paradoxically, religious expression is all the more real, meaningful, and transcendent because it is new each time even if it is as old as the world. Each time a religious act involving food is performed, it is experienced by the body in the moment of receiving, smelling, and tasting, and this strengthens feelings and beliefs about the presence of holiness in the activity.

Because of the ambiguities in some traditions associated with the body, food and eating can be powerfully complex signs of both the profane and the sacred. The “perfect ones” in dualistic groups like the ancient

Manichees and medieval Cathars starved themselves to death in rejection of the body and all things earthly. Fear of the female body particularly has driven the ascetic impulse in several religious cultures to sanctify the renunciation of food. Some early Christian writers associated female fasting with rejecting the sexual body, holding that the fasting body made virgins “more attractive” to Christ, their bridegroom (Shaw, 250–252). Lelwica and Griffith have noted parallels between traditional female holiness and dieting among contemporary American women.

### Food, Meaning, and the Secular World

While it is a common observation that religious tradition and belief have shaped diet and foodways in the past, modern observers tend to focus on the waning of religious influences on eating. Reformed Judaism, which does not require adherence to the dietary laws, is an example often cited. The persistence of irrational dietary traditions, as among the strictly kosher Hasidim, is viewed as a rejection of modernity.

Even people with a disenchanted, scientific worldview may unconsciously act according to sacred meanings. Ordinary profane experiences of eating may be meaningful bases for memory, reflection, and orientation and can be recognized as such to the extent that they are patterned on hidden sacred structures. Indeed, what constitutes a meal is often based on unconscious associations with primordial meals. Meals can return even the most secular person to another time and place. The language often used to describe such experiences is the religious vocabulary of symbol, myth, and ritual. American Thanksgiving, a secular holiday that celebrates consumerism as much as anything else, still centers on a meal modeled on sacral elements: sacrificial fowl and harvest fruits. What remains of its semireligious origins is perhaps a quick prayer and traditional dishes (some of rather recent origin). As anyone who has tried to vary a Thanksgiving menu knows from familial reaction, the sacred survives in turkey, stuffing, and mashed potatoes.

Furthermore, postmodernity has seen many conscious attempts at re-enchantment through foodways by those exhibiting what Eliade called “nostalgia for origins.” Elizabeth Ehrlich’s recent memoir of her progression from being a secular Jew to keeping the kosher kitchen of her foremothers is a good example.

### Summary

Examining connections between food and religion helps to illumine how religion functions in cultures, and why religious experiences are powerful for believers. It can also underline the fact that food feeds many hungers. Scholars have only just begun to examine the myriad ways in which this is true for religious peoples. It is safe to say that most scholars of religion would agree that religions provide humans with meaning-making structures that often involve food. These structures reveal the essence of the sacred through eating, sacrificing, preparing, or serv-

ing food to believers. They may serve as paradigms for all ordinary foodways as well. This domestication of sacred foodways in turn helps to perpetuate the process of meaning-making that is the function of religious practice and belief. Believers may or may not reflect on the importance of food for their religious identity. Knowledge of food’s centrality for meaning-making is not limited for believers to theological abstraction. To use Ronald Grimes’s phrase, it is more often felt “deeply into the bone” through the rites of preparation and consumption that help to order life every day as well as to mark special occasions. Brillat-Savarin’s “Tell me what you eat and I’ll tell you who you are” translates in the words of one woman recently interviewed after cooking a family meal, “Food is Judaism for me. I don’t think about it. It’s who I am.”

**RENAISSANCE BANQUETS.** The banquet, as a particular form of festivity, flourished in Renaissance Europe from the mid-fourteenth century to the early seventeenth century. It began as a specifically secular celebration; in medieval times the "feast" (French *fête*, Italian *fešta*) referred primarily to religious celebrations, special days in the church calendar—Easter, Christmas, saints' days—although it also denoted a sumptuous meal. As a lavish, ceremonial meal in honor of an individual or exceptional occasion, such as a wedding, the new banquet observed no such periodicity, and in its conspicuous consumption tended toward a blatant demonstration of wealth and power. It was distinguished not only by its extravagance and ostentatious scale but also by its theatricality and use of symbolism.

In the sixteenth century a banquet could also refer to the less ostentatious—though no less lavish, in relative terms—annual ceremonial dinners of *confréries* or guilds, groups of men linked through their craft or their parish. Usually held on a relevant saint's day, these were not only a ritual celebration but also a demonstration of goodwill.

### Origins and Etymology

Elaborate, extravagant, ceremonial meals had been offered before the adoption of the word "banquet." Descriptions of the dinners in honor of Pope Clement VI in the mid-fourteenth century, which included a centerpiece of a fountain spurring forth five different types of wine, show that lavish entertainment was nothing new. Nevertheless, the "banquet" must have differed in some way if a new word had to be brought into the language.

Initially, it appears, the banquet was a lavish meal presented in a different style, with various dishes set out on a long table, as would be a buffet today. Both the term and the event had their origins in fourteenth-century Italy. The Italian word *banchetto* derives from *banco*, 'a long bench or table'. "*Insieme disinano e cenano con banchetti molto abondevoli di varii cibi e bonissimi vini*," wrote the Italian Matteo Bandello in the early sixteenth century ("Together they dine and sup, the tables displaying a great abundance of diverse dishes and excellent wines").

The French term *banquet*, which entered common usage around the middle of the fifteenth century, and the Spanish *banquete* (documented early sixteenth century) were both borrowed from the Italian; in England the word "banketti," derived directly from the Italian, predated the French term *banquet*, adopted early in the sixteenth century. By this time the form of the banquet had evolved considerably, according to the accounts of Christoforo di Messisbugo, and included theatrical and musical performances.

In his capacity as steward at the court of the dukes of Este, Messisbugo orchestrated many banquets and in his book, *Banchetti: Compositioni di vivande et apparecchio generale* (1549), he describes, in unparalleled detail, the

management and staging of these lavish, formal, ceremonial feasts, from the setting of the tables with several tablecloths and ornamental figures of sugar or marzipan to the accompanying music and the dances performed during the course of the meal.

In sixteenth-century England the banquet evolved in two different directions. As well as an opulent and stage-managed feast, it became an elaboration of what had previously been the final course of a grand dinner, the dessert, an array of sweetmeats often served in purpose-built banqueting houses in the parks of great houses, or in an outside arbor or summerhouse.

### Banquet Food

One of the most striking features of banquet food was the presence of sugar, for both visual and symbolic effect, the lavish use of this expensive ingredient underlining the host's magnificence. The banquet menus appended to the printed edition of the *Viandier* of Taillevent (c. 1315–1395) in the last decade of the fifteenth century suggest an extravagant and incongruous application of sugar to roast quail, chicken and pigeon. (Originally compiled in the fourteenth century and attributed to the royal chef Taillevent, *Le Viandier* represents one of the few records of the cuisine of medieval northern France. The late-fifteenth-century printed edition contains additional material not included in the early manuscripts.) The chapter titled “Banqueting and made dishes with other conceits and secrets” in Gervase Markham's *The English Hus-wife* (1615) is composed of recipes for essentially sweet dishes such as fruit tarts, marmalades, preserves, marzipan, and jelly.

Sugar was used in dishes such as jellies, blancmange, and quince paste, and on dishes such as fritters and pies (Italian *torte*). It was an essential ingredient in the candied nuts and spices offered at the end of the meal, in jewel-like glazed fruits often hung on miniature trees of silver, and in decorative marzipan figures and in sculpted sugar table ornaments. For a banquet given by don Ercole, son of the duke of Ferrara, to a group of nobles including his father, Messisbugo ordered a sugar model of Hercules and the lion, colored and gilded, to decorate the table; with the final course of *confetti* came more sugar models representing Hercules defeating the bull, together with Venus, Cupid, Eve, and other mythical figures.

Because the banquet was itself an exceptional meal, banquet food had to be out of the ordinary (out-of-season asparagus, gilded and silvered calves' heads). This typically translated as the most prestigious, most expensive ingredients—meats such as veal and capons—prepared in the most elaborate, spicy ways so as to emphasize the art and skill of the cooks (which, in turn, reflected glory back on the reputation of the family). It also meant many services, each usually composed of several dishes, although it was not expected that everyone would eat something from every service—dishes were to be admired as much as consumed. The banquet offered by Gaston

### LA CONDAMNATION DE BANQUET

In the late fifteenth-century French morality play *La Condamnation de banquet*, *banquet* was an additional meal, differentiated from *dîner* and *souper* by the absence of servants; an array of food was set out on the table and guests helped themselves. It was also differentiated from the other two meals by the refined, elaborate dishes on offer, including a selection of sweet tarts, custards, fruits and nuts together with sweetened spiced wine.

Since the purpose of this play was probably to demonstrate the price of overindulgence, it should not be assumed that in fifteenth-century France the banquet was a supplementary evening meal, following the two standard meals of *dîner*, around midday, and *souper* in the early evening. In the play, the three meals are personified; after enjoying the hospitality of *Dîner* and *Souper*, the happy group of revellers—rejoicing in such names as Gourmandise, Friandise, Bonne Compagnie (Good Company), Passe-Temps (Leisure)—are led on, by Banquet, to a banquet. Here, however, they find they have been double-crossed as a horde of maladies (Gout, Colic, Jaundice, Quinsy) attack them. Those guests who escape bring a case before Dame Experience who finds Banquet, and to a lesser extent, *Souper*, guilty of corrupting the guests. Banquet is executed, and *Souper* is ordered to keep a respectable distance from *Dîner*. It is clear that the banquet was seen as promoting a pleasure-seeking lifestyle which, given the importance of the sin of Gluttony, would hardly have met with church approval.

IV, count of Foix, in honor of the ambassadors of Hungary in 1458 was comprised of seven services punctuated by four *entremets*; some of Messisbugo's menus ran to ten services, each composed of six or more dishes.

Especially when elements of performance were included, banquets could last many hours, and often led into a ball. At don Ercole's dinner, after all the courses and all the performances, the guests danced until daybreak, “*fino al giorno chiaro*” (until the light of day).

### Entremets

Designed to appeal to all the senses, banquets increasingly incorporated musical and theatrical elements. The *entremets*, the between-courses *divertissements*, were spectacles incorporating elements of surprise and trickery to amaze and impress the guests. Often elaborated to honor the occasion or the guest of honor, they were additional elements inserted in the structure of the meal.

In the fourteenth and fifteenth centuries, entremets were often the product of the kitchen, elaborated under the charge of the head cook, although they might well have involved carpenters and costume makers as well. The cooks' contributions included pastry castles, pies filled with live birds, gilded roast chickens and sucking pigs and fire-breathing roast swans and peacocks, re-dressed in their plumage. Almost invariably, music in some form accompanied the presentation of these entremets.

By the sixteenth century the entremets had undergone a transformation, with the culinary and theatrical elements separated. The between-course entertainment consisted almost entirely of performance—music, mime, dance, and acrobatics—leaving cooks free to devote all their skills to culinary artistry and visual display.

The banquet for don Ercole, for example, began with the performance of a comedy by Ariosto, after which guests moved to another room where they were entertained with music while tables were being set with silver candelabra, silver salt cellars, and intricately folded serviettes, or napkins. On their return they washed their hands in perfumed water before the dishes of the first service were presented, to the accompaniment of music and song.

Messisbugo specified precisely the vocal and instrumental complements to each of the services, continuing through the interval between services, as well as the performance of a group of Venetian jesters.

### Banquet Symbolism

Since the *raison d'être* of a banquet was to honor an occasion such as a marriage involving powerful and wealthy families, or the visit of a noble guest, or the arrival or departure of a prince (when it was often associated with the dramatic ritual of a procession), then it was necessary to highlight this purpose, typically through the entremets and table decorations. The sugar sculptures of Hercules at don Ercole's banquet were a clear reference to his strength and power, just as the recurring theme of a castle symbolized might and authority.

If the role of the banquet were to promote or strengthen strategic alliances (and marriages could easily fall into this category), the entremets might be designed to flatter the guests of honor. Thus at the dinner offered the Hungarian ambassadors the entremets presented paid homage to the guests and their mission. The first, a large castle atop a rocky peak, was decorated with the banners

## BANQUET OF THE PHEASANT

Because of their political significance, banquets often attracted the attention of chroniclers. One of the best known is the Banquet of the Pheasant, held at Lille in February 1454, which was thoroughly documented by Olivier de la Marche, who helped organize the event for Philip the Fair, Duke of Burgundy. The ostensible purpose of this banquet was to inspire knights to join a crusade to recapture Constantinople, recently taken by the Turks.

The chronicler says little about the food and wine, but a great deal about the visual effects. The banquet took place in a large room, decorated with tapestries depicting the life of Hercules, in which were three tables, each displaying a series of entremets. On the first was a delicately constructed church, a model of a naked young boy pissing rosewater, a ship laden complete with cargo and sailors, and a fountain, fashioned partly of glass, and surrounded by trees, fruit, and flowers of glass. On the second table was a large *pasté* (a pastry case) in which were twenty-eight musicians, while from another castle jets of orange-flower water sprayed into the moat and the figure of a man atop a barrel in a vineyard invited guests to help themselves. On the third table was a forest with wild animals, moving as if they were alive, ac-

cording to Olivier de la Marche. On a tall dresser were displayed platters of gold and silver, together with crystal jugs decorated with gold and precious stones. Near the wall were two high pillars, one supporting the figure of a woman whose right breast gushed spiced wine, and the other a lion, guarding the woman.

After admiring these, the guests were seated and a series of musical and other diversions followed, culminating in the presentation of a white-clad lady, representing the church, who pleaded to be rescued, her speech incorporating the motto of the Crusades, *Dieu le veut* (God wills it; or, God's will be done). At the end of her lament a live pheasant, richly ornamented with gold and jewels, and the duke (who, noted our diarist, knew exactly his purpose in organizing this banquet) made his vow to save Christianity, whereupon other nobles followed his example. After yet more music and spectacle, the dancing began, hippocras and candied spices were served, and guests enjoyed themselves until two or three in the morning.

## AN ITALIAN RENAISSANCE WEDDING BANQUET

Banquet celebrating the marriage of the Marquis Gian Giacomo Trivulzio with Beatrice d'Avalos d'Aragona, Milan, 1488.

1. Rosewater-scented water for the hands  
Pastries of pinenuts and sugar  
Other cakes made with almonds and sugar, similar to marzipan
2. Asparagus (to the amazement of the guests, since it was enormous and out of season)
3. Tiny sausages and meatballs
4. Roast grey partridge and sauce
5. Whole calves' heads, gilded and silvered
6. Capons and pigeons, accompanied by sausages, hams and wild boar, plus delicate "potages"
7. Whole roast sheep, with a sour cherry sauce
8. A great variety of roast birds—turtledoves, partridges, pheasants, quail, figpeckers—accompanied by olives as a condiment
9. Chickens with sugar and rosewater
10. Whole roast sucking pig, with an accompanying "brouet"
11. Roast peacock, with various accompaniments
12. A sweetened, sage-flavored custard
13. Quinces cooked with sugar, cinnamon, pinenuts, and artichokes
14. Various preserves, made with sugar and honey
15. Ten different "torte," and an abundance of candied spices

and coat-of-arms of the king of Hungary and the visiting nobles while the second, a fire-breathing tiger, bore the royal coat-of-arms on its collar.

Banquets also served to demonstrate, on a grand scale, the generosity of the host and, obliquely, his wealth and influence. Commenting on the growing popularity of banquets in northern France in the second half of the fifteenth century, Olivier de la Marche notes that their splendor accrued as each noble who gave a banquet wished to outclass the previous one. Their political importance meant that an element of social obligation was also involved; Messisbugo records the banquets don Ercole gave as well as those at which he was a guest.

Sumptuous, wealth-displaying spectacles involving food and performance continued into the seventeenth century. Vatel, a French counterpart to Messisbugo, was

responsible for the organization of one such event in 1661 at the chateau of Vaux-le-Vicomte, to which the young Louis XIV was invited. Later at Versailles, Louis himself entertained on an even grander scale but by this time the term *banquet* seems to have referred simply to formal dinners, the Versailles extravaganzas being known as *fêtes*.

**RESTAURANTS.** Throughout much of recorded history, eating away from home and in a public place has been experienced as a burden rather than a pleasure. The emergence of restaurant going as an enjoyable, leisure time activity and of restaurants as spaces clearly distinct from cafés, taverns, inns, or brothels is a comparatively recent development. In the West, restaurant culture is no more than 250 years old (and, in many localities, it is much younger). In southeastern China, restaurants were already part of urban culture in the thirteenth century; Marco Polo was astonished by the lavish eating establishments he found in Hangzhou, where regional cuisines such as Szechwan and Honan were readily available. Yet if some cultures have a centuries-long history of public, commercial, gastronomy, many others do not. In many parts of the world, businesses clearly identifiable as restaurants have developed only in the past fifty years. They are the products of post-1945 developments in travel and trade, such as the emergence of global tourism and the spread of multinational corporations.

### Europe: Ancient, Medieval, and Early Modern

There were no restaurants in Europe or North America until the mid-eighteenth century, but food was often eaten away from home. In a time when people had neither running water nor refrigeration nor gas nor electricity, and when journeying between cities was a matter of weeks rather than hours, people often ate away from

their places of residence. Yet, they did not rely on restaurants. Travelers expected either to carry their own food or to depend on private hospitality; public eating establishments were viewed largely with suspicion and disgust. Since antiquity, numerous writers have accused innkeepers of fraudulent trade practices and unsanitary preparations: the classical medical authority, Galen, claimed that the innkeepers of Rome substituted human meat for pork! In a less spectacular vein, countless patrons over the past two millennia have complained of being served vinegar mixed with water rather than the wine for which they had paid. Affluent travelers therefore preferred to stay with friends along the way or to purchase raw ingredients and have meals prepared by the servants who accompanied them. This was the case even when traveling great distances, such as from London to Scotland during the Middle Ages. In the eighteenth and nineteenth centuries, the existence of many recipes for traveling sauces and portable soups attests to the continued disrepute of public eateries.

Throughout antiquity and the medieval period, shops or stalls selling hot food therefore catered not to the gastronomically adventurous but to the urban poor, whose rudimentary living arrangements made food preparation nearly impossible. In the southern Italian city of Pompeii (destroyed by volcano in 79 C.E.), taverns and *popinae* (foodselling establishments) clustered around the baths and gladiators' dormitories but were not to be found in the more prosperous parts of the city. Members of the Roman elite preferred to recline on couches while eating, but most food-retailing establishments were furnished only with tables and chairs. Ceremonial meals of many sorts played a significant role in the political and social life of Greece and Rome, but these were always held in private residences. Moreover, women were prohibited from these exclusively male events. In these and other ways, the food culture of Mediterranean antiquity was very different from that of the West today, in which restaurants play such a major role.

During the Middle Ages, the large numbers of religious pilgrims who traveled across Europe and into the Near East sought food and shelter in monasteries and in the hostels and hospices run by religious orders. In some areas, inns and taverns provided commercial hospitality but such establishments were rare outside of cities. Nor did even the most reputable inns fully escape stigma and suspicion. Taverns and alehouses were also common in much of western Europe, but these drinking places served only a few foods to soak up the alcohol. The association of public sociability with riotous drinking meant that these were also largely male institutions, at least in theory and imagery. In the seventeenth and eighteenth centuries, they were increasingly avoided by social and cultural elites of both sexes.

Well into the 1800s, inns and cookshops primarily served meals at a single large table, known in English as an "ordinary" and in French as a *table d'hôte* (literally,

"host's table"). These shared meals provided travelers with the opportunity (not always desired) to meet each other, but they were better suited to the regular habits of local patrons than to the erratic schedules and varied preferences of passing voyagers. Service was "French style," that is, all the different dishes were placed on the table at once and customers were expected to help themselves to whatever was in front of them. This arrangement worked well for any assertive patrons seated near the roast at the middle of the table, but it could be frustrating for shy or foreign-language-speaking guests positioned with the condiments at the far corners. Given that the food was all placed on the table simultaneously, it was also inconvenient for travelers who arrived fifteen minutes after the meal had begun.

### The First Restaurants

Scholars agree that the first self-styled "restaurateurs" opened for business in Paris during the 1760s, but there is some disagreement as to the significance of these establishments. For many years, a man named Boulanger has been credited with having been the first to have sold a wide variety of choice dishes and to have served them at small, oilcloth-covered tables in his shop on the rue des Poulies. Since the early nineteenth century, it has also been usual to cite the tale of Boulanger's dispute with the city of Paris's guild of cook-caterers (*traiteurs*) over the precise status of his signature dish, sheep's feet in sauce. Lore and legend says that in 1765 the cook-caterers tried to shut down Boulanger's shop because the dish infringed their legal monopoly on the sale of all *ragoûts* (dishes cooked in a sauce). Some authors claim that the cook-caterers won their lawsuit and others say they lost, but all use this story to support the broader contention that restaurants were largely impossible until the French Revolution of 1789.

The Boulanger story has been repeated and embellished until it has become one of the most familiar items in the culinary-history, but its sources are largely apocryphal. First briefly noted by P. J. B. Le Grand d'Aussy in his 1782 *Histoire de la vie privée des françois* (History of the private life of the French), an early, encyclopedic venture in writing the history of food and eating, Boulanger's adventures were a popular subject with nineteenth-century antiquarian scholars keen to show how much Paris had changed since the Revolution. However, this account of the origins of restaurant going assumes that the desire to "eat out" has been largely constant throughout history and needed only the cookery talents of one man and the legal changes of one Revolution to take the form familiar today. It cannot explain how the restaurateurs of the 1760s overcame centuries of prejudice against "public cooks" and tells us little of the real importance of this new form of service. Recent scholarship, therefore, places the development of restaurant culture within broader social and historical contexts. It looks for changes not only in what was being cooked and by

whom, but in the entire social and cultural framework. The first self-defined restaurateurs built on Enlightenment ideas about science and sentiment; in doing so, they created a cultural institution distinct from the eating-houses and inns of earlier periods.

Restaurateurs in mid-eighteenth-century Paris took their name from the “restorative bouillons” in which they specialized. Made by sweating large quantities of veal, game, and poultry over high heat, these bouillons were concentrated meat broths deemed beneficial for those who were too weakened by illness or exertion to eat an entire solid meal. As they were also costly to prepare, it is hardly surprising that these bouillons were most often recommended to members of the urban elite (both male and female). Within the fashionable culture of the day, the inability or reluctance to eat a full meal was a sign of emotional and intellectual, as well as physical, sensitivity. The first restaurateurs did not cater to customers who were hungry and hurried; rather they provided a milieu in which people could make public show of their private sensibility. Opulent furnishings, mirrored walls, and porcelain consommé dishes all ensured an environment distinctly different from the hurly-burly of the tavern or inn.

In the long run, the most important innovation of the 1760s and 1770s was in the form of service. Restorative bouillons had vanished from most restaurant menus by the 1820s but the basic features of restaurant service remained. These included seating groups of patrons at their own tables, serving meals at unspecified times, and providing a menu from which customers made their own choices. All these elements created the impression that restaurants provided individual and personalized service. Restaurants were public places, insofar as they had neither membership fees nor admission requirements, but they were public places where people went for privacy. Many Paris restaurants, such as the Maison Dorée and the Cadran Bleu, were especially distinguished by their private rooms (*cabinets particuliers*) that were ideally suited to romantic trysts and other secretive meetings.

### Restaurants in Nineteenth-Century Paris

Though they first emerged in the eighteenth century, restaurants are most commonly identified as institutions of nineteenth-century Parisian life. It is often said that they were instrumental in democratizing formerly aristocratic privileges: the one-time chefs of princes and dukes found themselves unemployed after their titled patrons fled France during the Revolution. A few early nineteenth-century restaurateurs made much of their aristocratic connections, but most restaurateurs had no such ties and were more closely linked to the other retail food trades. Antoine Beauvilliers, former pastry chef to the king's brother, did open a well-known restaurant, but he did so before the Revolution and much of his fame came from the cookbook, *L'art du cuisinier* (The cook's art) that he published in 1814.

Poster advertising the Grand-Café Zürcherhof in Zurich, Switzerland. Large establishments such as this, with the added amenities of a billiard academy and theater, became popular in many parts of Europe at the turn of the twentieth century. Art Nouveau lithograph by P. Krawutschke, 1908. ROUGHWOOD COLLECTION.

One important development of this period was the distinction of two types of service: *prix fixe* (fixed price) and *à la carte* (from the menu). In the former, the customer ordered from a restricted number of items but was guaranteed to have a two- or three-course complete meal for the price specified. With service *à la carte*, the diner had the freedom to order anything listed on the menu but may have been surprised at the size of the final bill. In the 1820s and 1830s, these were two separate types of establishments (the latter usually being more prestigious), but today it is not uncommon to find both forms of service available in a single restaurant. Indeed, since the 1970s, a shift has occurred, such that a comparatively brief menu, restricted to locally available, seasonal ingredients, is now often seen as the mark of an upscale restaurant, while the lengthy menu parading hundreds of items is looked at with derision.

Based on early nineteenth-century texts, a short listing of the most famous first restaurants would have to include the following: Véry's (at the peak of their fame, the Véry brothers ran two prominent restaurants, one in the Palais Royal and the other in the Tuileries Gardens); the Rocher de Cancale on the rue Montorgueil (famous both for oysters and for the epicurean singing societies that met in its private rooms); the Trois Frères Provençaux (three business partners who introduced some of the cookery of southern France to the capital—they were especially known for their *brandade*, a dish of puréed salt cod, traditionally eaten on Good Friday); Méot's and Robert's (two well-known establishments of the late 1790s); the Café Hardy (despite its name, a restaurant noted for its grilled meats); and LeGacque's (home to a famous eating club, the Wednesday Society). Many restaurants of a slightly later period play a significant role in the realist novels of the 1830s and 1840s, especially those of Honoré de Balzac. At the end of the century, restaurant and café scenes featured prominently in the works of some Impressionist artists.

Two businesses currently in operation often make claims to be the oldest restaurant in Paris. These are the Tour d'Argent, housed in a sixteenth-century inn, and the Café Procope, a famous meeting place for eighteenth-century intellectuals. Since neither actually started as a restaurant *per se*, some may dispute their right to this title. Other old restaurants still in operation include the Véfour in the Palais Royal (converted from café to restaurant in 1817) and LeDoyen's on the Champs Elysées.

### The Spread of the French Model

The use of French names for restaurants in many parts of the world indicates the nineteenth-century predominance of the Paris model. Two of the first restaurants in Sydney, Australia were named after two of the most famous ones in Paris, the Trois Frères Provençaux and the Café-Restaurant de Paris. Another famous Paris restaurant name, Véry's, was replicated in central London, where Verrey's was a Regent Street fixture from the 1850s to the 1920s. In Mexico City, the Tivoli and Maison Dorée restaurants borrowed their names and their menus from the French capital.

By the first decades of the nineteenth century, restaurants may have been fixtures in the Paris landscape but they were still uncommon in the French provinces and even more rare elsewhere. As late as the 1850s, American and British visitors to Paris remarked on how strange and marvelous it was to be offered the choice of dozens of different dishes and to eat those dishes in an ornate dining room surrounded by groups of both men and women. Many of London's exclusive gentlemen's clubs were famous for their chefs (Louis Eustache Ude at Crockford's Club and Alexis Soyer at the Reform Club are just two examples) but these clubs, restricted to members only and forbidden to women, were not the same as restaurants. An important British institution, gentlemen's

clubs were copied in the colonies, especially India, where the Bengal Club (Calcutta) was founded in 1827. For members of the Victorian middle class, domestic comfort played a central part in defining their own national, social, and gender identities. Many Britons therefore looked askance at restaurants as offering proof that the French had no real home lives and, hence, no sense of family.

### Hotel Restaurants and "International" Cuisine

The luxurious hotels of the late nineteenth century played an important part in introducing restaurant culture to the British and North American upper classes. These sumptuous hotels with their grand entrance lobbies and ornate dining rooms were made possible, in part, by the greatly expanded travel habits that developed with the railroad and the steamship. The French model remained preeminent in hotel restaurants for several reasons, including that country's long established reputation for luxury goods and Paris's international appeal. The standardization of a *haute cuisine* (high cookery) that came to be identified with "French" food and the rise of hotel training programs may also have played a role. Georges-Auguste Escoffier, a chef who worked closely with the hotel entrepreneur, César Ritz, is often credited with having rationalized restaurant kitchen work in a fashion that made it easier to teach and replicate. His cookbooks and menus were often copied and his way of organizing kitchen work became standard practice.

Until the *nouvelle cuisine* and fusion foods of the last third of the twentieth century, Escoffier's version of "international cuisine" dominated the hotel restaurants and so-called "fine dining" establishments of much of the world. This cuisine was international insofar as it was served to diners in grand hotels around the globe, but the recipes, ingredients, and seasonings were western European in inspiration. In many parts of the world, the introduction of this so-called "international" cookery and Western-style restaurant service went hand in hand. Organizations such as the Japanese Travel Bureau (a joint venture between government and private railroad, steamship, and hotel companies, founded 1912) actively encouraged the establishment of "European restaurants" where Western travelers would find forks and knives, printed menus, and meals served in several courses. Tea-houses (frequented only by male customers) and Japanese restaurants (*ryōri-ya*) were already widespread, but concern to show Japan as a "civilized" (i.e., Western) country led to new businesses that were furnished with tables and chairs, served large quantities of meat, and severed all ties to prostitution. During the following decades, and especially with the Allied occupation after World War II, businesses and government alike were keen to promote an image of Japan as a country that foreigners would find both reassuringly comfortable and pleasantly exotic. This demand was met by restaurants in which service duplicated that to be found in Paris, Chicago, or

New York, but where the dining room was decorated with chrysanthemums, bamboo, and cherry blossoms and the menu might include a few notionally Japanese dishes.

### Early Restaurants in the United States

As was true of Europe, colonial North America had taverns and boarding houses, but no restaurants. Coffee houses and oyster houses began appearing in the late eighteenth century, but the word “restaurant” was not commonly used until the 1830s or 1840s. Delmonico’s, which opened in Manhattan in 1831 and occupied several different locales until it finally closed during Prohibition, is often cited as the first American restaurant but this is far from certain. Nonetheless, whether it was the first or the fifty-first, Delmonico’s became a model throughout the nineteenth century. In 1868, the first railway restaurant car in the United States was named “Delmonico’s” even though it operated on the Chicago-Alton line, half a continent away from New York. Charles Ranhofer, chef at Delmonico’s from 1863 to 1895, helped spread the restaurant’s fame in the pages of his enormous cookbook, *The Epicurean*, which also included anecdotal stories about the famous patrons he had met and the great meals he had cooked.

Scenes of adulterous dalliances and tipsy festivities, restaurants such as these were as infamous for scandal as they were famous for food (lobsters and champagne were the usual fare). Central to one stereotype of New York nightlife, they were largely irrelevant to many of the city’s inhabitants. It should not be forgotten, however, that the lavish scale of turn-of-the-century restaurants and hotels depended on the existence of a largely immigrant underclass from which staff members were drawn. Indeed, the East Coast restaurant and hotel labor market at this time was effectively segregated by ethnicity and gender. Eastern and southern European women worked as maids, and African-American women were employed as chambermaids in the grandest hotels, while most waiters were men of French or Italian descent. Although the food served was French in name or inspiration, most of the chefs were German; French men worked as waiters or as specialized cooks, such as pastry chefs.

### Mass Market Restaurants in the United States

The grand hotel restaurants of the late nineteenth century were fixtures in major cities, but they fed only a small percentage of the American population. Unlike earlier taverns or oyster houses, the lobster palaces and cabarets welcomed both men and women but this gave them an air of promiscuity that worried cultural conservatives, religious leaders, and prohibition activists. Levenstein has argued that Prohibition, by dissolving the association of eating out with alcohol consumption, did much to make eating away from home acceptable for single women and members of all social classes. It is certain that the 1920s witnessed both the closing of many of the most luxurious barrooms and the opening of numerous lun-

cheonettes and tearooms. (It remains unclear, however, whether Prohibition caused these changes or whether Prohibition and luncheonettes were both responses to other, more fundamental, changes in American society.)

By the 1930s, the U.S. Bureau of the Census counted 200,000 food-retailing outlets, including 124,000 restaurants and over 45,000 lunch counters. The latter category included drugstore soda fountains, sandwich shops, and diners as well as hot-dog stands and box-lunch companies. It is interesting to note that the Census Bureau included automats and self-service cafeterias under the heading of restaurants.

According to Richard Pillsbury, the postwar period did not see an immediate boom in the number of restaurants, but it did witness the transformation of American culture that was crucial to their eventual growth. Changes in family life, increased urbanization, the omnipresence of the automobile, and the affluence of the middle classes all contributed to making restaurant meals a regular part of life for many Americans. Drive-in restaurants made it possible to “eat out” within the comfort of one’s very own automobile. Yet variation by region and by socioeconomic class should not be overlooked. Nor should it be forgotten that eating places in the South were often segregated, and that interracial “dine ins” played a significant part in the Civil Rights movement of the 1960s.

In the last quarter of the nineteenth century, Fred Harvey developed one of the first restaurant chains, in cooperation with the Atchison, Topeka, and Santa Fe Railroad. Along the route, he built and operated seventeen Harvey Houses, which were recognizable by their décor and by the waitresses’ identical uniforms. The menus were coordinated, however, to guarantee that the restaurants’ pleasing familiarity did not extend to the food served, and the traveler was guaranteed of never being served the same fare two meals in a row. This show of variety under an umbrella of uniformity has been the hallmark of restaurant chains ever since.

Prior to World War II, chain restaurants were comparatively novel, accounting for only 15 percent of all restaurant business. (In contrast, chain grocery stores in the 1930s were already responsible for nearly half of all grocery sales.) Howard Johnson’s, initially a New England ice cream chain, expanded along the highways of the 1930s and 1940s much as Harvey House had along the railroads.

In the late twentieth century, franchised businesses have accounted for much of the U.S. restaurant industry’s expansion. In 1994, nearly 60 percent of the total 406,000 U.S. restaurants were chain units and 200,720 restaurants belonged to chains that included over 200 units. Many of these were fast-food establishments such as McDonald’s, Burger King, or Kentucky Fried Chicken, but many others were full-service restaurants such as the Outback Steakhouse, the Olive Garden, Benign’s, or Denny’s. The success of these chains suggests

that customers value familiarity. Eating out has become routinized.

### Ethnic Restaurants

So-called “ethnic” restaurants may seem a logical outgrowth of the waves of immigration to the United States in the late nineteenth and early twentieth centuries, to Australia in the same period, and to Great Britain in the period since World War II. In part, they are, for economic marginalization and racism have often caused recently arrived immigrants to concentrate in businesses requiring comparatively small capital investment, such as catering. Moreover, recruitment of new workers for these enterprises is usually done informally, through family and community connections, and further concentrates the members of an ethnic group in a few businesses. Since most restaurant employees do not actually speak to the customers, it is seen as an ideal line of work for recent immigrants who feel uncertain about their linguistic abilities.

Yet it should not be imagined that these restaurants have simply been transplanted from the immigrants’ home country. Nineteenth-century Greece had few, if any, restaurants (and the inns were as disreputable as they had been two thousand years before), but late-nineteenth-century Greek immigrants to the United States quickly became concentrated in the restaurant industry.

The food served in ethnic restaurants often constitutes a distinct cuisine. In all cultures and contexts, there are some foods that are almost exclusively eaten in restaurants and others that never are. (For example, one would have to read a great many U.S. restaurant menus before finding those two staples of the American diet, peanut-butter-and-jelly sandwiches and popcorn.) If we consider Indian restaurants in the United Kingdom, we find that by the 1990s, they employed more people (roughly 70,000) than the shipbuilding and steel industries combined. Many of these were staffed by immigrants from the province of Sylhet in the northeastern corner of Bangladesh, but the food served had its roots in other parts of the subcontinent. Ingredients and cooking methods from the northwestern region of Punjab dominate “Indian” restaurant food in much the same way that one version of “French” cooking was once the norm in Western restaurants. This may be because the 1947 partition caused many Punjabis to migrate to Delhi and other cities where they started running food stalls. When the Indian government established catering colleges in the 1960s to train employees for the tourist industry, the instructors came from these Punjabi families. Since they taught north Indian cooking, this was what the students learned, regardless of the students’ own ethnic or regional background.

### Working in Restaurants

Restaurants combine characteristics of both production and service industries. Since William Foote Whyte’s clas-

sic study, *Human Relations in the Restaurant Industry* (1948), social scientists have recognized that this combination leads to a conflict of interests between kitchen and dining-room employees. While the waitstaff must be constantly attentive to the demands and desires of the customers, the kitchen workers have their own distinct priorities. If a few famous chefs such as Paul Bocuse, Joel Robuchon, or Alice Waters seem to set the standards to which gourmets aspire, many other chefs and kitchen employees see themselves as ordinary, working-class, people, who have little in common with their middle-class and upper-middle-class patrons (see Fine, 1996).

Labor historians have long puzzled over the very low rates of unionization in restaurant work. One explanation is that the industry has largely institutionalized a system of informal rewards that would be lost with formal contracts: tipping encourages competition among members of the wait staff, rather than solidarity. Furthermore, waiting tables is commonly casual work rather than a life-long career. Finally, the antagonistic, often combative, relation between kitchen and dining-room employees means that no single union has ever had much success in reaching both groups of workers.

It may be difficult to imagine that the first restaurant kitchens were fueled by coal or wood, but so they were. Smoke-filled, sooty, and with little in the way of refrigeration, the restaurant kitchens of the early nineteenth century would appall any health inspector today. The Belle Epoque restaurant boom in Australia and elsewhere was made possible by the increasing ease of railroad transportation and the availability of refrigeration techniques, while it was made further profitable by the expansion of advertising. The steakhouses so popular in the Anglophone world of the 1950s and 1960s (such as the Steak & Ale chain in the United States or the Berni Inns of Great Britain and Japan) served Argentinean beef and a limited number of simple side dishes, all easily prepared by semiskilled labor. Today, much of the inexpensive food consumed in restaurants, like the convenience food prepared at home, is made possible by the introduction of microwave technology. Any account of the spread and standardization of the industry should also consider the growth of restaurant-supply firms.

### Restaurant Guides and Reviews

A. B. L. Grimod de La Reynière (1758–1837) is generally credited with having invented the restaurant review. His yearly *Almanach des gourmands* (Gourmands’ almanac), published in the first decade of the nineteenth century, pointed its readers to the finest restaurants, pastry cooks, and gourmet shops of Napoleonic Paris. A bestseller in its day, it also set the precedent for later ventures in restaurant reviewing. The advent of rail and automobile travel expanded the market for restaurant guides. The Michelin tire company published its first hotel/restaurant guide to France in 1900 and awarded its first stars in 1926. Since then, airlines and automobile manufacturers have often

ventured into the guidebook/cookbook business, though none have had the enduring importance of the Michelin guides and their rankings. Governments keen to promote tourism have also entered the business of publishing guidebooks and encouraging the hospitality industry.

In the mid-twentieth century, a somewhat different form of restaurant guide emerged, written neither by a lone gastronome nor by a faceless corporation. Duncan Hines (*Adventures in Good Eating*) in the United States and Raymond Postgate (*Good Food Guide*) in the United Kingdom both promised to publish recommendations sent by their readers. Postgate did this much more than Hines, but both contributed to the idea that members of the ordinary eating public might have their opinions heard. In the early twenty-first century, thousands of amateur reviewers made their opinions known on their own websites.

### Why People Do Not Go to Restaurants

The idea of voluntarily going out to eat sits uneasily with the teachings of many religions. People who obey Jewish, Moslem, Jain, or Hindu dietary laws may find it no easier to eat in a Michelin three-star restaurant than in a stockyard or petshop. Both Jewish and Moslem law prescribes how livestock should be slaughtered. Unless an eatery is run by a known member of the community, observant patrons may not be willing to eat the meat served there. Brahmans, members of the highest Hindu caste, are forbidden to eat or drink anything prepared by a member of another caste. In addition, only other Brahmans are supposed to see them eating. Many Orthodox Hindus of all castes are highly reluctant to consume food (or even drink water) prepared and brought by unknown hands, even when traveling long distances. Jains are so profoundly vegetarian that they refuse to eat food prepared by someone who is not, even if the meal includes no animal products. None of these dietary laws can be obeyed in a restaurant where the cook remains unknown to the diner. In such a context, a restaurant meal can be only an ordeal.

As mentioned above, British middle-class culture, with its emphasis on domesticity, was slow to adopt the custom of eating out. In the late 1800s, the famous grill-room, Simpsons in the Strand, tried to attend to cultural norms by offering separate dining rooms for men and women. Lower down the social scale, working-class Britons in the early twentieth century might sometimes rely on takeout from local fish-and-chip businesses, but the association of restaurants with upper-class Francophilia meant that they, too, were unlikely to go out to eat. In many respects, then, it was not until the 1950s and 1960s that restaurant culture became a significant part of British life.

### Why People Go to Restaurants

In many parts of the world, certain specialty foods are rarely, if ever, prepared at home and the chance to eat

Many large department stores feature restaurants where shoppers may take lunch or dinner. The restaurant at Harrods, Knightsbridge, London is both a fashionable eatery and retail shop for gourmet food products. © BO ZAUNDERS/CORBIS.

them may be one incentive for eating out. For example, local businesses limited to the time-consuming and messy business of preparing tripe are common in France, Greece, and Portugal. In Japan, only licensed chefs in specialist restaurants are allowed to prepare the highly poisonous blowfish (fugu). In China, snakes are never eaten at home but they are nonetheless considered a great delicacy when served by restaurants that specialize in them.

It may seem paradoxical, but food is rarely the only reason that people go out to eat. The evidence of the past several centuries indicates that restaurants may serve many different functions. Even within a single dining room, some customers may be celebrating a wedding anniversary and others may be cheating on their spouses. By entertaining guests or meeting friends in a restaurant, people can shield their domestic lives from others; in France today, only the very closest friends are ever invited into the home. In moments of domestic conflict, eating in the comparatively public space of a restaurant

may be a way to reestablish the outward forms and appearances of civility.

As publicly accessible places in which patrons are seated at their own tables and eat their own meals, restaurants seem to provide a window into other people's private lives. The elaborately mirrored dining rooms of many nineteenth-century restaurants made it especially easy to observe one's fellow patrons without staring at them directly. Diners could preserve the illusion of their own privacy, even as they peered into that of others. Since the 1980s, there has been a brief trend toward very large and loud restaurants where the crowded atmosphere may further blur the distinction between private and public. There has also, however, been a renewed interest in intimate private dining rooms far from the eyes of star-struck strangers and the ears of curious waiters.

The various "ethnic" restaurants found in American cities in the 1930s were distinguished more by their furnishings and music than by their cuisine. Today's cult of culinary authenticity may scoff at the notion that red lacquer walls and a Pekingese under the table suffice to make a restaurant "Chinese," but it is important to recognize that many supposedly national cuisines have been produced by the demands of restaurant culture.

**RETAILING OF FOOD.** In agricultural societies all over the world, food marketing took place in central marketplaces in towns and cities. In larger cities, specialized merchants operated temporary stalls and permanent warehouse/stores alongside farmers who brought produce and animals directly to market. The Greek agora is an example of such a marketplace. The ruins of Pompeii provide examples of merchant's streetfront stores.

Expanding industrialization in the late nineteenth century ushered in mass consumerism in the United States and Europe. New forms of food purveying transformed the structure of the food business, the nature of retail ownership, and the social relations of food shopping. Innovations in food shopping that developed in the late nineteenth and early twentieth centuries spread throughout the world with varied significance and direction.

#### Victorian Food Halls, Public Markets, and Local Family-Owned Stores

Mass production created both new commodities and a new professional-managerial consumer class in the late nineteenth century. Grand emporia, called "department stores," developed in response to this new type of customer. Centrally located, these palaces of consumerism used elegant, monumental ambience to display commodities. Early department stores usually incorporated food halls in which high-end customers were introduced to new products at separate stations in sanitized settings. Samples and demonstrations of new products were offered.

At the same time, large public markets continued to purvey fresh produce and meat brought directly from the country to central markets where they were purchased by the working classes, servants to the middle classes, and the small-scale vendors of raw and cooked foods who served dispersed communities.

#### Corporate Chains and Supermarkets

During World War I and the interwar years, the inflation of food prices made the high cost of living a major political issue. In the 1920s and 1930s new forms of food stores were invented in the United States to rationalize costs. This occurred in a two-step process, with centralized chain stores followed by the new self-service supermarkets. The Atlantic and Pacific Tea Company (A&P) was the largest of the early chain stores. Expanding from a chain of tea stores to encompass all food products, A&P was concentrated mostly in the Northeast. Other pio-

neering chains were Safeway in the West and Krogers in the Midwest. Chains achieved economies of scale through buying in bulk and a higher volume of sales. A&P also relied on its own production of house brands to cut wholesale costs.

The first chains in the United States retained the same spatial/social organization as family-owned counterparts. Clerks still presented wares over the counter and helped make selections, gave product information, often bargained over price, and arranged for such services as credit and delivery. This changed with the advent of self-service marketing. Michael Cullen, an employee of Krogers, opened his first self-service King Kullen store in New York in 1930 when Kroger executives rejected his new concept. Recognizing that larger stores were necessary to achieve profitable sales volumes, self-service emerged as an adaptation to size. Cullen's stores were ten times larger in square footage than chain stores. As James Mayo reports (p. 117), the term "supermarket" came into use in the 1930s and was defined by a threshold sales volume, parking lots, and self-service.

## FOOD HALLS IN JAPAN

In Japan, where efficient public transit has forestalled reliance on cars, supermarkets are less developed, and small family-owned stores and chain-owned convenience stores near neighborhood public transit are heavily used. In addition, department stores located at major transit junctions devote much space to food halls. These food halls provide offerings ranging from perishable produce and sushi to a broad selection of cooked dishes representing traditional Japanese, other Asian, and European cuisines. Hawkers use traditional calls to attract customers to their stands, reproducing the ambience of the old urban marketplace for middle-class housewives and office workers within this modern, sanitized site of overconsumption.

Window display of a high-class London fruiterer, 1918. All of the produce shown in the window is sourced by country of origin and name of fruit variety. ROUGHWOOD COLLECTION.

Showcasing the product is an important aspect in retailing food. Here forty-eight flavors of ice cream are displayed behind fancy chocolates (under the glass). PHOTO FROM THE 1940S COURTESY OF H. WILLIAM ISALY AND BRIAN BUTKO.

In self-service stores, goods were displayed to allow the consumer to make autonomous choices based on fixed prices. Also referred to as “cash and carry” stores, they did not provide the conveniences, such as credit or delivery, that formerly bound merchant to customer. Instead they provided an often desirable anonymity and private decision-making. The grocery cart was developed in 1937 and expanded the possibilities for bulk shopping. Increasing automobile and refrigerator ownership enabled infrequent bulk shopping to replace frequent or daily shopping..

These enterprises were important sites in the development of a mass market of middle-class consumers. The United States, unlike Europe, lacked a history of aristocracy and strong class distinctions in taste. Media advertising used specials and brand imaging to shape consumer desire for standardized, reliable mass-produced foods and to foster trust in corporate chains.

In contrast, Europe retained clearly marked class distinctions in taste and consumption. An active food co-op movement was at the center of debates about food prices. Traditional wholesalers and their shopkeeper allies had considerable political clout. They promoted the benefits

of artisan production over mass production in food processing. Independent grocers and wholesalers fought successfully for protectionist legislation to thwart chain-store development and the food co-op movement. According to Victoria de Grazia in her article, “Changing Consumption Regimes in Europe” (pp. 71–74), this protest occurred particularly in Germany, France, Austria, and Italy, in contrast to Great Britain and Sweden.

### Post-World War II Global Trends

Supermarkets became the dominant sites for food shopping in the United States during the post-World War II era of abundance. As technology was fetishized to symbolize modernity, supermarket architecture and design became strikingly modern, emphasizing service by machines rather than people. Innovations in shelving, lighting, open refrigerator cases, and newly designed promotional displays highlighted the abundance of products and encouraged impulse shopping. Furthermore, as mass ownership of automobiles enabled the sprawl of suburban settlements, new stores in developing suburbs were less densely distributed and much larger in size, drawing customers from long distances.

In the postwar era in Europe, traditional state-protected food distribution was rapidly transformed. Self-service stores in Germany increased in number from 39 in 1951 to 17,132 in 1960 and 35,000 in 1965. At the same time in France, the “hyperstore” was invented, joining food with other consumer goods in even larger stores. Promodes, a provincial Normandy food wholesaler, merged with two rival family firms in the 1960s and within a decade developed a multinational retail network.

### ETHNIC MARKET SUCCESSION

In Philadelphia, a multiblock area called the “Italian Market” served originally as a site where Italian immigrants could purchase fresh seasonal produce grown by Italian truck gardeners in southern New Jersey, as well as imported cheese and oil. Butchers slaughtered pigs in the fall and made sausages for Christmas Eve celebrations and the long winter. In spring, paschal lambs were available. Today, the area is still identified on tourist maps as the Italian Market. Yet aside from the remaining cheese and sausage purveyors and a few venerable restaurants, most vendors and consumers are Vietnamese who are now dominant in this area and have special ethnic food needs.

## THE SUPERMARKET IN DEVELOPING COUNTRIES

Supermarkets require private transportation for bulk purchases. In developing nations, chains such as Carulla in Colombia develop as soon as automobile suburbs emerge. Aspiring middle-class people without cars often pool their resources to use transportation such as unlicensed taxis and buses to take them shopping in these outlets.

Another major French chain, Carrefour, opened its first North American hyperstore in Montreal in 1973, and by 1989, there were eighteen European-style hyperstores in the United States. Today many supermarket chains are truly global in ownership and in the commodities that are purveyed. In 1979, A&P itself was bought by Tengelmann, a German-owned multinational. At the same time, U.S. corporations such as Pathmark have created "superstores" that sell more than food.

### Post-Industrial Reaction and Counterreaction

Today, many consumers see drawbacks in corporate food distribution. Centralized stocking practices are far removed from local customer needs as they rely more on corporate relations with food manufacturers and formulas for profit margins. In spite of the illusion of unlimited choice, variety in packaging and a parade of "new" products that are minor variations of existing ones, provide a limited veneer of novelty. Long-distance produce, cultivated for preservation and not for taste, is limited in its variety. Moreover, supermarket shelves are dominated by the products of a few large conglomerates whose power facilitates shelf preference and agreements to exclude competing products.

As corporations cut back on labor costs, workers are fewer and less knowledgeable. Meats once handled by skilled butchers are now packaged in the processing plant. As service declines, work is transferred to the customer. Huge stores mean a longer time spent walking down the aisles and waiting on checkout lines. Surveillance cameras limit one's privacy.

However, for certain urban populations, small stores remain central. Post-industrial capitalist elites who aestheticize food and leisurely eating, as those in the Italian-initiated "Slow Food" movement and their global counterparts, eschew mass-produced foods and long-distance produce. They are served by artisan bakeries, homemade-pasta shops, and local farmers markets. In-

creasing numbers of global immigrants are served by small shops that have ethnic foods and merchants who speak their languages. In addition, poor people in inner cities avoided by chains are dependent on small high-priced stores.

Seeking a broad customer base, corporate chains are continually responding to new demands. As people become more and more pressed for time, dispersed convenience stores allow quick purchases by people on the run. Prepared-food offerings and salad bars have expanded in supermarkets. Chains of upscale markets, such as the Whole Foods network in the United States, have developed to address high-end consumer desire for fresh quality produce and gourmet take-out foods. At the other extreme are chains of huge stores like Costco and Walmart, which sell mass quantities at near wholesale prices. Some chains try to resocialize the impersonal space of food stores by providing eating spaces, sponsoring singles nights for young professionals, and reaching out to local communities through promotions for local schools.

## RICE.

*This entry includes three subentries:*

The Natural History of Rice

Rice as a Food

Rice as a Superfood

### THE NATURAL HISTORY OF RICE

Rice has fed more people than any other crop has for thousands of years. The ancient Indian name for rice, *Dhanya*, means “sustenance for the human race.” Especially in much of Asia, life without rice has been unthinkable. Rice feeds more than half of the world population, but most rice is consumed within ten miles of where it is produced.

Rice is the second largest crop in planting acreage after wheat. Global rice production was 596.5 million tons from 155 million hectares (ha) in 1999. The major rice growing regions are found in more than a hundred countries in Asia, Latin America, and Africa. But major rice exporting countries only include Thailand, the United States, Vietnam, Pakistan, and India. About 85 percent of total rice production is for human consumption. Rice provides 23 percent of the global human per capita energy and 16 percent of the per capita protein (IRRI, 1997). In Asia, where people typically eat rice two or three times a day, 250 million rice farms (the average rice land per farm is less than 1 ha) produce more than 90 percent of the world’s rice. For example, Myanmar consumes 195 kg of rice per capita per year, whereas the average annual rice consumptions in Europe and America are 3 kg and 7 kg, respectively. The three most populous nations, China, India, and Indonesia, are rice-based countries, which together have 2.5 billion people (about half of the current world population).

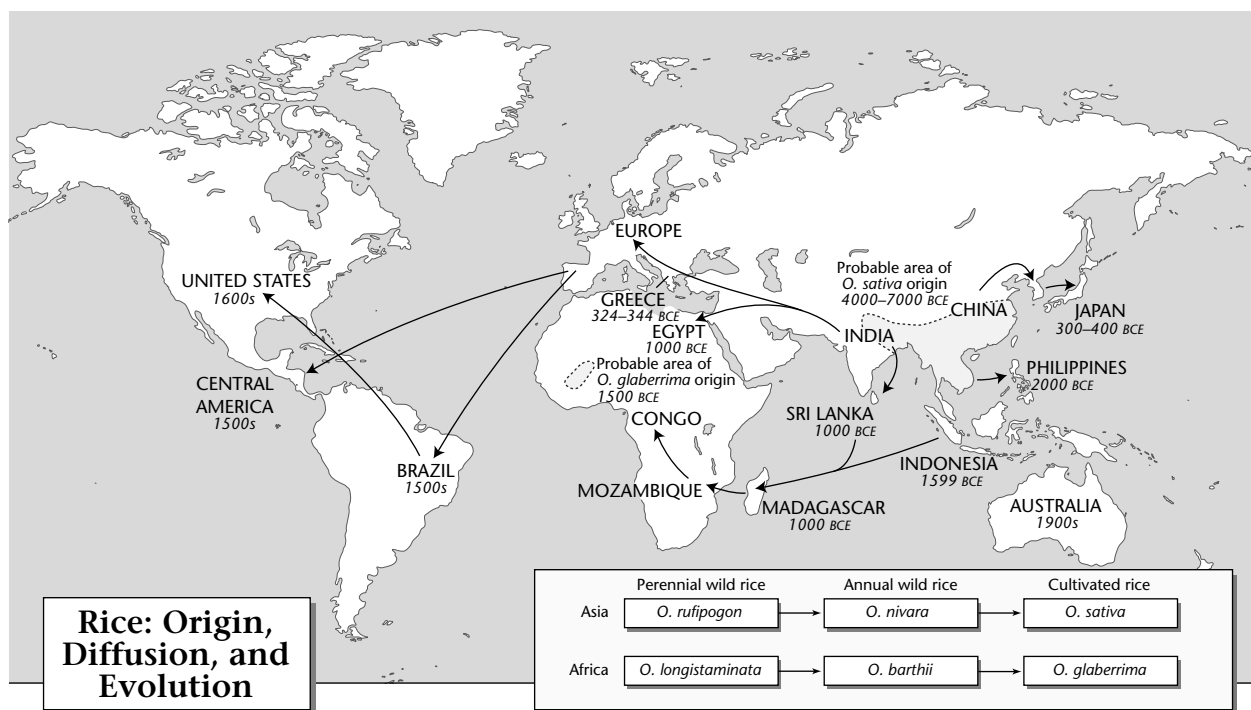

Rice can be processed into rice bran oil, wine, rice cakes, and other foods. Rice flour can be used as the main component of face powders and infant formula or for polishing expensive jewelry. Rice bran oil can be used in cooking, making soap, and as an ingredient in insecticides. Silica-rich rice husks can be used as raw materials for construction materials such as insulation, as a conditioner for commercial fertilizers, as an ingredient in hand soaps and furfural (a chemical used in synthetic resin manufacture), as mulch, as an abrasive, as a fuel, or as an ingredient to make thermoplastics (Yekani Amonollah: United States Patent: 6,172,144). Rice straw has been used for livestock feed, bedding for livestock, straw mushroom production (in China and Thailand), and in industries for arts and crafts. In early times, rice straw was also used for thatching roofs in Asia, and to make ropes, mats, paper, baskets, and bags. Now rice straw is mostly used for animal feed or as field manure.

### Rice Biology

**Classification.** Rice has 120,000 varieties, the richest gene bank in the plant kingdom. There has been great

progress in rice genome sequencing projects recently by using both *Indica* (9311) and *Japonica* (Nipponbare) varieties. This will greatly enhance rice improvements in the near future. From the taxonomy of rice, Asian rice belongs to the grass (Gramineae) family and genus *Oryza*. Wheat, corn, and barley also belong to the grass family. *Oryza* has twenty-three species, which can be classified into four groups. The *O. ridleyi* complex and *O. meyeriana* complex contain species in lowland swamp forests and upland hillside forests, respectively. The *O. officinalis* complex consists of perennial species throughout the tropics. The *O. sativa* complex includes two cultigens and the wild relative of these two cultigens. Only two *Oryza* species, the tetraploid *O. schlechteri* and the diploid *O. brachyantha*, are different from these four groups. Based on another classification method for *Oryza* species, the common wild rice or so-called *O. perennis* complex includes Asian wild rice (*O. rufipogon*), African wild rice (*O. longistaminata* or *O. barthii*), and Oceanian wild rice (*O. meriodinalis*) (Chang, 1976). *O. rufipogon* is the wild relative of *O. sativa* and a noxious weed in rice-growing countries. This wild rice has the characteristic of easy shedding to facilitate easy dispersal and easy crossing with the Asian cultivars, which results in the degradation of the variety and contamination of red-grained plants. The wild rice (or Indian rice or water oats) of North America (*Zizania palustris* or *Z. aquatica* L.,  $2n = 30$ ) belongs to a different genera and even a different tribe of the grass family. It was traditionally harvested by native Americans in the Great Lakes region, and now is commercially produced in Minnesota, Wisconsin, northern California, and Manitoba, Canada. It has nutty and rich flavor and boasts a pleasant chewiness. It is high in protein and B vitamins but low in fat.

Rice has only two cultivated species, *Oryza sativa* Linn. (the Asian cultivated species) and *Oryza glaberrima* Steud. (the West African cultivated species). *O. sativa* is by far the more widely utilized of the two. By contrast, *O. glaberrima* has much less diversity because of a relatively short cultivation history and a narrower dispersal than *O. sativa*. The main differences in botanical morphology between these two cultivated species are the ligule size and glume pubescence. Most of *O. glaberrima* varieties have fewer hairs, short ligules, and fewer or no branches, and also have red-hulled grains on the shattering panicle. They are generally more resistant to flood, alkaline soils, and blast than *O. sativa* varieties. Another difference is that *O. glaberrima* is strictly annual, whereas *O. sativa* is potentially a perennial. It is generally thought that there are two major subspecies in *O. sativa*: *indica* (or *hsien*) and *japonica* (sometimes called *sinica* or *keng*). *Japonica* is generally short, less leafy, and has a strong culm and short grains. *Japonica* varieties are grown in temperate areas such as northern China, Japan, Korea, Spain, Australia, and California. When cooked, *japonica* rice is sticky. *Indica* rice generally has long, slender, and fluffy grains, many tillers, and is tall, leafy, and tolerant of

drought. It does not stick when cooked. *Indica* rice is usually grown in hot (tropical or subtropical) climates such as in India, Thailand, Vietnam, and Southern China. The so-called *javanica* can be classified as a tropical *japonica* and is mostly grown in Indonesia and the United States. *Javanica* was originally grown in equatorial areas with abundant water and is generally vulnerable to drought.

**Morphology.** Rice has the following three main developmental phases: the vegetative phase (from germination to panicle initiation), the reproductive phase (from panicle initiation to flowering), and the ripening phase (from flowering to maturity). A typical rice plant during reproductive and ripening stages has the following organs: roots, a main stem and a number of tillers (or side shoots), leaves, panicles, flowers (or florets) when flowering, and grains when maturing. The edible part of a rice plant is in the rice grain, which includes glumes, endosperm, and embryo. Some varieties have awns at the tip of the grain. More detail about rice morphology can be found in literature by Chang and Bardenas (1965) and by Grist (1986).

Rice has a fibrous root system, that is, it has temporary seminal roots or embryonic roots, then secondary adventitious roots. The fibrous roots only last for a short time after seed germination. An alternative is the classification of rice roots based on the spatial pattern as crown roots (including mat roots) below the soil and nodal roots above the soil. The function of rice roots is to absorb water. It is estimated that it takes 5,000 liters of water to produce 1 kg of irrigated rice. Owing to the great consumption of water in rice production, future rice culti-

vation will face the looming water deficiency in some countries.

Plant height can range from approximately 0.4 m to more than 6 m (in floating rice) depending on the rice variety or environmental conditions. The rice culm is round, hollow, jointed, and hairless. A maturing rice plant has a main stem and a number of tillers depending on the variety and cultural conditions. Each stem has a certain number of nodes (generally ranging from 13 to 16 nodes) and internodes under a certain environmental condition for a rice variety.

Rice leaves are rather flat. The first rudimentary leaf or prophyllum is at the base of a tiller and, with only a two-keeled bract, has no blade. The uppermost leaf immediately below the panicle is called the flag leaf. The leaf blade and leaf sheath are attached at the node, where there is an auricle (a pair of claw-like appendages encircling the stem), and the ligule (a thin, upright papery and triangular structure) immediately above the auricle. When young, the major difference between rice and a common grassy weed (*Echinochloa* spp.) is the presence of auricles and ligules.

Rice has a terminate panicle having the following structures: the base, axis, primary, secondary, and sometimes tertiary branches, pedicel, rudimentary glumes, and spikelets. Each panicle generally bears from 50 to 300 flowers or spikelets.

The rice panicle is a perfect and determinate inflorescence. A rice spikelet has two sterile lemmas, the

Horses threshing rice in the Italian Veneto. From a copper engraving in Gian Battista Spolverini's *La coltivazione del riso* (The Cultivation of Rice) printed at Verona in 1758. ROUGH-WOOD COLLECTION.

rachilla and the floret. A rice floret includes six stamens and a pistil having stigmas, styles, and ovary, enclosed by the lemma and palea, sometimes with an awn. Even though rice is pollinated by wind, the natural crossing rate is low (less than 3–4%) because of the floral characteristics. The stigma (a plumose structure) functions to catch pollen for fertilization. This function is important for the out-crossing rate in hybrid rice seed production.

The rice grain generally refers to rough rice or paddy consisting of brown rice (or caryopsis) and the hull. Brown rice consists of the endosperm, embryo, and several thin layers of differentiated tissues—the pericarp (the ovary wall), the seed coat, and the nucellus. The seed coat consists of six layers of cells, with the aleurone layer the innermost. The rice embryo is small and contains the embryonic leaves (plumule) enclosed by a sheath (coleoptile), embryonic primary root (radicle) ensheathed by the coleorhiza, and the joining part (mesocotyl). Rice endosperm consists mostly of starch granules in a proteinaceous matrix, together with sugar, fats, crude fiber, and inorganic matter. Hull weight is about 20 percent of the total grain weight. The hull of a typical *indica* rice variety has the palea, lemmas, and rachilla, but the hull of *japonica* rice usually only includes rudimentary glumes and perhaps a portion of the pedicel. The lemma is usually tough, archmenlike, sometimes awned, and bigger than the palea. Generally, pigmentation in rice does not cause any problems except for the pigmented apiculus or hull, which may stain the endosperm during parboiling, thus affecting the marketing value. Grain ripening stages (15–65 days) can be subdivided into milky, dough, yellow-ripe, and maturity stages based on the texture and color of the growing grains.

**Nutrition.** According to the U.S.A. Rice Federation (May 2002), half-cup servings of white rice and brown rice contain 103 calories and 108 calories of energy, respectively. The composition of typical brown rice, milled

rice, rice bran, and germ or embryo are indicated in Table 1. Although the nutritional value varies with different varieties, soil fertility, fertilizers applied, and other environmental conditions, the following trends still exist by comparison with other cereals: lower fat content after the removal of the bran, lower protein content (about 7–10 percent), and higher digestibility of proteins. Fresh harvested rice grains contain about 80 percent carbohydrates, including starch, glucose, sucrose, dextrin, fructose, galactose, and raffinose. Polished rice grains have an insufficient supply of iron, considerable Vitamin E content, rich pantothenic acid, pyridoxine of Vitamin B complex, low riboflavin content, negligible vitamin A and D content, and an unfavorable calcium to phosphorus ratio.

Milling, rinsing before cooking, and boiling reduce the nutritional value of rice. For example, milling removes about 80 percent of thiamine from brown rice, thus causing beriberi and other dietary deficiencies. However, most rice consumers still prefer well-milled rice since brown rice has an unfavorable chewier texture and flavor.

**Protein:** Crude protein content in rice can be measured using micro-Kjeldahl analysis and other methods. In addition to varietal differences, protein content is affected by environmental conditions, such as soil and nitrogen fertilizer application. Protein is mainly distributed in the bran and periphery of the endosperm. The central part of the rice grain only contains a small proportion of rice's protein. Rice protein has all essential amino acids, in rather a well-balanced proportion, for the human body. Though the amount of protein is not high, the quality of rice protein is one of the highest. Rice protein has a biological value of 86, compared to 75 to 90 of the biological value in fish fillet protein. Rice is unique in the richness of alkali-soluble proteins or glutelin (about 70 percent), whereas the other cereals are rich in alcohol-soluble proteins or prolamin (rice has only about 3 percent prolamin in its gross protein content). The other components of rice proteins include 4 to 9 percent water-soluble proteins or albumins and about 10 percent salt-soluble proteins or globulins. Rice proteins are rich in arginine and contain tryptophan and histidine, but are poor in lysine and threonine. However, by comparison with other cereals, rice protein is one of the most nutritious because it contains about 4 to 5 percent lysine (higher than that in wheat, corn, or sorghum). Efforts have been made to improve protein content through conventional breeding, but so far, it has not been successful. Rice varieties with high protein contents tend to have worse flavor, are less tender, less cohesive when cooked in the same amount of water, and longer cooking times are needed because of lower water absorption.

**Carbohydrate:** More than ninety percent of the energy in rice comes from carbohydrates. Rice contains both simple and complex carbohydrates. Simple carbohydrates or sugars include glucose, fructose, lactose, and sucrose.

Complex carbohydrates in rice are starch and fibers. As for fiber, one-half cup cooked brown rice and the same volume of cooked white rice have 1.6 grams and 0.3 grams of dietary fiber, respectively. About 85 percent of the rice grain weight is starch. Amylose is the linear fraction of the rice starch, and is negatively correlated with the cohesiveness, tenderness, color, and the gloss of the cooked rice. The rice starch has to be gelatinized during cooking or else rice is too firm to be eaten comfortably. Glutinous or waxy rice, sometimes referred to as “sweet” or “mochi,” contains 1 to 2 percent amylose, has white and opaque kernels, and often is used for such ethnic foods as mochi cake and crackers, desserts, puffed rice, and par-boiled rice flakes. The nonglutinous rice varieties can also be classified as low-amylose (8–20 percent), intermediate (21–25 percent), and high-amylose (>25 percent) types. Generally *Japonica* has low amylose content and the amylose content of *indica* varies widely. Environmental conditions can greatly influence amylose content as much as 6 percent for the same variety in the different seasons. Intermediate amylose content is preferred by the major world rice market. For high-amylose rice varieties, a gel consistency test can complement the amylose test by separating these varieties into three categories: hard gel consistency for very flaky rice (<40mm for the length of gel), medium gel consistency for flaky rice (41–60 mm), and soft gel consistency for soft rice (>60 mm).

**Fat:** Rice contains a trace of fats (0.9 and 0.2 g of fats in a half-cup of cooked brown rice and a half-cup of cooked white rice, respectively). Rice is a health food because it does not contain any cholesterol, but it does contain linoleic acid, accounting for 30 percent of the total rice fats that cannot be converted from carbohydrates, proteins, or other fats.

**Vitamins:** Rice contains several kinds of vitamins (Table 1). Thiamine (vitamin B<sub>1</sub>) has positive health effects for the brain and heart, but unfortunately it cannot be stored in a human body and must be supplied in the daily diet. One half-cup of cooked brown rice and a half-cup of cooked white rice contain 7 percent and 6 percent of the U.S. Daily Value (D.V.) for thiamine, respectively. Riboflavin (vitamin B<sub>2</sub>) is important for energy production and the health of skin and eyes. Rice has a very small amount of riboflavin, about 1 percent of the D.V. in one half-cup of cooked brown rice. Niacin (vitamin B<sub>3</sub>) is essential for healthy skin, digestive, and nervous systems. One half-cup of cooked brown rice and the same amount of cooked white rice have 8 percent and 6 percent of the D.V. for niacin, respectively. Pyridoxine (vitamin B<sub>6</sub>) indirectly helps to control amino acids in the body. A shortage of pyridoxine has negative effects on the central nervous system. The folate or folic acid is important for the manufacture of DNA and hemoglobin. Rice also has traces of vitamin E that protects vitamin A and essential fatty acids from oxidation. Recently, scientists in Switzerland and Germany developed “Golden Rice<sup>TM</sup>” through genetic engineering and substantially increased vitamin A content in rice (Ye et al., 2000).

**Minerals:** Iron is important in humans for oxidation and other enzymatic reactions. One half-cup serving of cooked brown rice and one-half-cup serving of cooked white rice have 8 percent and 7 percent of the D.V. for iron, respectively. Phosphorus is critical for healthy bones and teeth and other metabolisms. Phosphorus in rice can be best absorbed when supplemented with milk or vegetables. One half-cup of cooked brown rice and a half-cup of cooked white rice have 8 percent and 3 percent of

the D.V. for phosphorus, respectively. Rice also has traces of calcium, potassium, and sodium.

**Rice grain quality.** The aroma of rice can be detected in rice leaf tissue, rice kernel, and cooked rice. It was reported that 2-acetyl-1-pyrroline was a major aroma component in aromatic rice. There is an excellent description about the evaluation of rice grain quality in a book chapter by Webb (1985). Grain quality is determined by the appearance (milling quality), texture and ease of cooking (cooking quality), flavor and smell (eating quality), nutritive characteristics, cleanness, and purity. For parboiled rice, light-hulled (straw-colored) rice is preferred and bran color should have uniform light color. Rice can be classified, based on the grain length on the traditional U.S. market, as follows: extra long (>7.50 mm), long (6.61–7.50 mm), medium (5.51–6.60 mm), and short (<5.50 mm). Rice also has the following classification based on the grain shape (measured as length/width ratio): slender (>3.0), medium (2.1–3.0), bold (1.1–2.0), and round (<1.1)

Endosperm is preferred to be bright, clear and translucent by the market, with the exception of waxy rice having an opaque endosperm. Excessive chalkiness is undesirable because chalkiness greatly affects the milling yield and milling quality. Chalkiness can be categorized as white belly, white core, and white back depending on the location of the chalkiness on the rice endosperm. Chalkiness is influenced both by the variety and by environmental factors such as weather conditions when harvesting, and by different agronomic or field managements.

Milling quality is determined by the following factors: size and shape of the grain, ripeness, drying method, age, moisture content, and the method of storage. High head rice and high milled rice are critical for the commercial success of a rice variety. To determine the milling quality, the rough rice percentage is measured after removing the foreign materials (dockages). After removing hulls and most of the bran layers and germs, total milling yield and head (or whole-grain) rice yield can be measured. Total milling yield includes the whole (head) rice and broken rice yield from total unclean rough rice.

The economic value of rice depends on its cooking and processing quality, which can be measured in terms of major methods: amylose content, alkali spreading value, gelatinization temperature, gel consistency, and protein content. Sometimes, parboiling-canning stability and specific brewing cookability with malt diastase need to be measured for specific purposes. The gelatinization temperature is the temperature at which 90 percent of the starches in the rice have gelatinized or turned liquid and lost their crystalline structure. Gelatinization temperature can be evaluated by measuring alkali spreading value (ASV). Gel consistency is used to differentiate among the high-amylose rice varieties with different amylograph pasting viscosities. The major factors affecting gel consistency are fat (lipid) content and degree of milling.

## History

**Origin and diffusion.** Origin and diffusion of rice are still unsettled issues (Huke and Huke, 1990). Asian cultivated rice originated in the region from south China to the Ganges in South and Southeast Asia, including the river valleys and deltas of the Brahmaputra of northern India, the Irrawaddy of Burma, the Mekong of Vietnam, and the Yangtze of China. Based on the number of wild rice species and the evidence of rice glumes in the burnt clay from the late Neolithic period, Ting (1949) concluded that rice might have originated in South China and then spread northwards. Copeland (1924), Chang (1975) and some Japanese rice scientists asserted that rice might have originated from South or Southeast Asia, including India, China, Thailand, and Indonesia. Thermoluminescence and carbon-14 tests of the pottery shards with the imprints of rice grains in Thailand indicate that rice could be dated back to at least 4000 B.C.E. (IRRI, 1997). The three oldest pieces of archaeological evidence for rice origin are from Maharaja of India (6500–4500 B.C.E.), Non-Nok-Tha of Thailand (about 6000 B.C.E.), and Pen-tou-shan of China (7150–6250 B.C.E.) (Abrol and Gadgil, 1999; Chang, 1998). Great diversity of rice and linguistic evidence support the argument for Southeast Asia as the origin of rice cultivation. It was believed that the early spread of rice was from southern China or northern Vietnam to the Philippines about 2000 B.C.E., and then to Indonesia about 1599 B.C.E. by Deutero-Malayans. Most likely, the techniques of rice cultivation radiated outward from the Yangtze delta of China towards Korea and then Japan. Japan became known as *Mizumono kuni* (the Land of Luxurious Rice Crop) about 300–400 B.C.E., but rice did not become the staple Korean dish until the 1930s. Sri Lanka had rice as a crop as early as 1000 B.C.E. Rice was introduced to Greece and the neighboring Mediterranean c. 344–324 B.C.E., and then gradually to Europe and Africa (IRRI, 1997). There have been debates about the introduction of Asian rice into Africa. *O. sativa* was believed to have been introduced to Africa primarily from Malayo-Polynesia a few centuries B.C.E. or from Sri Lanka and Indonesia. It was postulated that at different times *O. sativa* was introduced to Egypt from India, to Madagascar from Indonesia as early as 1000 B.C.E., to Mozambique and East Africa from Madagascar, and finally to West Africa by Portuguese spice traders between the fifteenth and seventeenth centuries, or by traders or Muslim missionaries in the ninth or tenth centuries. Lu and Chang (1980) argued that Asian rice entered into the Congo from Mozambique in the nineteenth century. The other possibilities for the introduction of rice into Europe are from Persia, central Asia, or directly from China. Later the Portuguese brought rice to Brazil, and the Spanish introduced rice to Central and South America. The Malays brought rice to Madagascar. The United States might have been first introduced to rice from the Malagasy Republic, Europe, or the Far East. It was often cited that a storm-battered ship from Madagascar had brought rice seeds “Golde

Seede Rice” to South Carolina in 1694. Not until 1888 did the first large-scale growing of rice plants occur in Louisiana and Texas, although rice was introduced to Virginia as early as 1609. Later the Gulf Coast grew rice because of the popularization of mechanical farming. The current major rice-producing states in the United States include Arkansas, California, Louisiana, Texas, Mississippi, and Missouri. Rice was first commercialized in Australia in 1924, even though in as early as 1892 experimental planting of rice took place in New South Wales.

It was believed that *O. glaberrima* originated in the central Niger river delta of Mali about 1500 B.C.E. (Portères, 1956). Two secondary centers of diversity are located to the southwest near the Guinean coast. *O. glaberrima* has two ecotypes, deepwater and upland, and is now only grown in the flooded area of the Niger and Sokoto River basins. *O. glaberrima* in some parts of the Africa was gradually replaced by *O. sativa*. The ongoing rice improvement project of the West Africa Rice Development Association is also targeting these regions by substituting new varieties for *O. glaberrima* through *glaberrima-sativa* interspecific crossing.

**Domestication.** Chang (2000) made exhaustive descriptions on the evolution and early spread through several routes for rice, especially Asian rice. In his review the pattern for rice evolution was suggested as from perennial wild to annual wild and then to cultivated. Therefore, the evolution for *O. sativa* is *O. rufipogon* to *O. nivara* to *O. sativa* in Asia. In parallel, the evolution for *O. glaberrima* is *O. longistaminata* to *O. barthii* and then to *O. glaberrima* in Africa. It is believed that rice originated in the marsh areas and spread toward the dry lands and hills. The domestication of rice, including such cultural practices as puddling and transplanting, might have first taken place in China. The ancient Chinese cultural practices for rice then shifted to Southeast Asia and other parts of the world (De Data, 1987). Only in the twentieth century did systematic rice improvement start. For example, IRRI scientists Peter R. Jennings, Te-Tze Chang, and Henry M. Beachell developed the semi-dwarf variety “IR8” in 1966, which initiated the “Green Revolution” (Lang, 1996). China also successfully developed hybrid rice in 1973. These achievements have greatly increased the rice yield so as to feed the increasing world population, especially in Asia.

Oka (1988) indicated that domestication of rice involves decreased seed dormancy, increased seed shattering and selfing rate, and other adaptive characteristics. Wild rice usually has one month or more of seed dormancy resulting in nonsynchronous germination. This is an adaptive characteristic to increase the probability of regenerating success under changing environments. Seed maturity on a panicle also does not synchronize and the flowering for wild rice can last more than one month instead. Grain dormancy protects rice grains from sprouting on panicles because of frequent raining during

These Vietnamese rice paddies are not only used for growing rice, they are sometimes flooded for fish farming, and ducks can be raised in the paddies while the rice is young. PHOTO COURTESY OF THE NATIONAL ARCHIVES AND RECORDS ADMINISTRATION.

ripening. Generally, *Japonica* has little dormancy, but *Indica* has some degree of dormancy. The tropical *Indica* in particular has quite strong dormancy. But grain dormancy is affected by the weather. For the same variety, sunny and dry weather will make the grain less dormant than humid weather. It was deduced that the substance(s) for grain dormancy exist mainly in the flowering glumes and the hull (palea and lemma) because dormancy was broken by simply removing the hull from the seed. Grain dormancy can be broken by chemicals, such as fungicides or diluted nitric acid, or by heat treatment (50°C for four to six days or even longer).

Grain shattering is affected by the strength of the spikelet attachment to its pedicel. The requirements for the resistance to grain shattering vary with the environmental and cultural conditions in the modern rice cultivation. Regions with strong winds at rice maturity require non-shattering varieties. Intermediate-shattering types should be grown for mechanical harvesting using a combine. If harvested by hand harvest and threshing, the intermediate type with resistance to shattering is preferred. In Asian rice, *Japonica* is highly resistant to shattering, but most *Indica* varieties have intermediate resistance to shattering. Wild rice has easy shedding or shattering and thus easy dispersal. Also, some wild rice has awns on the tip of the grain. Some rice varieties are either fully awned or partially awned among spikelets on the same panicle. This characteristic might be favorable for dispersal through water. The cross-pollinated feature of wild rice (similar to that of wild barley) might be favorable for rice evolution.

**Hybrids.** Before the 1970s, rice breeders extensively studied the utilization of rice heterosis after they realized the great potential of using heterosis to improve crops such as corn. Generally speaking, hybrid rice has more

than 15 to 20 percent yield advantage over the best conventional rice varieties in China, Bangladesh, Brazil, Colombia, Ecuador, India, Indonesia, Malaysia, Myanmar, the Philippines, Sri Lanka, and Vietnam. Unfortunately, no large-scale planting of hybrid rice was successful until China developed a three-line (cytoplasmic male sterile line, male sterile maintainer line, and restorer line) system hybrid rice in 1973 and commercialized this technology in 1976. This was because of the very small reproductive organs and difficulty in finding or developing a cytoplasmic male sterile line in rice. China has greatly increased its rice production by the utilization of hybrid rice technology and therefore has been able to feed its rapidly growing population in the last quarter of the twentieth century. Now China is trying to increase the rice yield by employing the two-line system hybrid rice (male sterile line and restorer line) and intersubspecific heterosis (i.e., the heterosis between *Indica* and *Japonica*) utilization. By following China's success, other countries, including India, Vietnam, Myanmar, and Bangladesh, are currently learning to use the hybrid rice technology to boost the rice yield. FAO is also providing financial support to activities of networks on hybrid rice such as the International Task Force for Hybrid Rice and the Working Group on Hybrid Rice in Latin America and the Caribbean (GRUTHA). Outside China, the planting acreages under hybrid rice in Vietnam, India, and Bangladesh in 1998 were 250,000 ha, 120,000 ha, and 20,000 ha, respectively.

## Production and Processing

**Distribution.** Generally speaking, the rice paddy is adaptable to regions that have sufficient rainfall, high temperature, and prolonged solar radiation. Rice has evolved into four major ecosystems based on different ecological or environmental conditions: irrigated (53 percent of the total rice crop area, exemplified by China), rain-fed lowland (23 percent), deepwater (11 percent), and upland (13 percent, exemplified by Latin America). Rice is cultivated on all continents except Antarctica. Recent estimates list 112 rice-growing countries, including all the countries in Asia and most of the countries of West and North Africa, some countries of East and Central Africa, most of the South and Central America countries, and Australia (De Datta, 1987). Geographically, current rice cultivation regions range from latitudes 53° N in Moho, China, to latitudes 35° S in central Argentina and New South Wales, Australia, from sea level in Bangladesh to an altitude of 3,000 m in Nepal. Asia produced 90.6 percent of the total rice production in 1999; Latin America, 4 percent; Africa, 3 percent; Europe, 0.5 percent; Australia, 0.2 percent; and the United States, 1.6 percent. The ten countries with the largest rice production in 1999 were China, India, Indonesia, Bangladesh, Vietnam, Thailand, Myanmar, Brazil, Japan, and the Philippines, in descending order. Outside Asia, rice is consumed as a staple food in Guyana, Guinea, Liberia, Sierra Leone,

and Madagascar. Based on the above geographical distribution of rice, currently there are three major international rice research centers from Consultative Group on International Agricultural Research (CGIAR), including the International Rice Research Institute (IRRI) in the Philippines, Centro Internacional de Agricultura Tropical (CIAT) in Columbia, and West Africa Rice Development Association (WARDA) in the Ivory Coast.

**Cultivation.** Rice can be grown in many ecosystems from upland to deepwater conditions. For the irrigating system, fields are plowed with a wooden plow, and then a harrow drawn by a docile and reliable water buffalo in most Asian countries. Some Asian countries, such as India and China, are still practicing transplanting the rice seedlings to suit for the double cropping or multiple cropping systems. Developed countries in Europe and America, such as the United States, employ direct seeding cultivation without transplanting, to avoid the cost of expensive labor and to take advantage of the advances in the mechanization of rice production. There are two methods for direct seeding: (1) dry seeding before sprouting, followed by a flow of water in Louisiana and Texas, and (2) wet seeding by low-flying aircraft in California and Arkansas because rice is unique, among cereals, in being able to germinate when submerged in water. In rice cultivation, the most serious pests include stem borers and leaf hoppers. The most dangerous diseases are rice blast, bacterial blight, sheath blight, and seedling blight. These pests and diseases can be controlled at the proper stage by chemicals or other measures. Now more efforts are being focused on breeding for resistant rice varieties through conventional approaches or through modern biotechnology, such as Bt. rice. The most persistent weeds in rice cultivation are barnyard grass (*Echinochloa spp.*), water hyacinth (*Eichhornia crassipes*), *Eleocharis acicularis*, *Typha* spp., and red rice. These weeds can be controlled by cultural approaches or by herbicides.

**Harvesting and post-harvest operations.** Rice is considered to be a photoperiod or daylength sensitive crop, although there are daylength-insensitive rice varieties. Short photoperiods or daylengths (less than 11 hours) will shorten its growth duration, which ranges from 90 to 160 days or even longer depending on the photoperiod sensitivity, the basic vegetative phase, and the temperature sensitivity. The approximate duration from flowering to maturity is thirty days. Photoperiod-insensitive rice varieties, such as most of the current rice varieties in tropical Latin America, are increasingly preferred because of their greater adaptability to a wide region and the flexibility in planting dates. But in some rice-growing regions, the strong photoperiod sensitivity of rice is used to grow rice in the rainy season; it is then harvested after the rainy season and before the dry season water shortage. The maturity of rice is also influenced by air temperature, planting methods, and nitrogen fertilization. The best time for mechanical harvesting is when panicles become yellow but the stem and leaves still have green color. At that

time the moisture contents of grains should be 20 to 25 percent. By visual inspection in the field, rice can be harvested when the kernels on the upper part of the panicle are fully ripe and the ones in the lower part reach a hard-dough stage. For some rice-growing regions with some extra time beyond one rice-growing region, ratooning of the first rice crop is possible by using the varieties with high ratooning ability for maximizing the annual rice yields without too much investment. Currently, harvesting can be done with a combine in the more developed countries. However, most Asian and African countries are still harvesting rice by hand sickles, scythes, or knives, because of scarcity of capital, availability of inexpensive labor, and the topographical limits, such as small rice fields, mountainous fields, or deep-water areas. A rice combine threshes the harvested paddy after cutting. Hand threshing or threshing by animals or simple foot- or gasoline-powered threshing machines is still being used in some countries.

**Storage.** Before storage, the moisture content of rice grains should be reduced to below 14 percent. The most convenient method is sun drying if the weather permits—drying rice grains in the open air and under strong sunshine for one to two days. But the sun drying method can produce “sun checks,” which reduce the head rice and increase the rice bran percentage; this method also requires intensive labor. Therefore, artificial drying such as batch dryers in Japan and the hot air dryers in the United States became an alternative to sun drying. The artificial drying can avoid rapid dehydration, which causes reduced head rice. The cleaning of rice grains is important to remove foreign seed and trash before storage. There are three major cleaning methods: air cleaning by using a hand winnower, mechanical cleaning by using sieves, and gravity cleaning. In rice mills, all impurities, odds and ends such as stones, and pieces of soil and straw must be removed by a screening or riddling process and a fan. Further removal of nails or bits of iron can be done with a magnet. Since aging through storage increases water absorption and paste viscosity and reduces solids dissolved in cooking water, cooked fresh rice tastes worse than rice with six to twelve months of storage because rice grains cooked immediately after harvesting tend to disintegrate and to be more cohesive. The curing process can be completed through keeping the rice in heaps of straw for several days or through domestic curing methods. However, long storage time should be avoided, especially for undermilled rice. Cooked rice, after several months of storage, becomes less sticky and more flaky. In addition to moisture, metabolisms of grain tissues, microorganisms, insects, and mites also causes storage losses.

**Milling.** Milling in the rice industry can refer either to the overall operations that include cleaning, hulling, pearling, polishing, and grading; or simply to one operation, removal of the rice bran or outer layers. Typically, the pericarp accounts for 1 to 2 percent of the weight of

the whole rice caryopsis, seed coat and aleurone 5 percent, embryo 2 to 3 percent, and endosperm 89 to 91 percent (Wadsworth, 1994). The edible part of rice grain is enclosed in the glumes, which need to be first separated by hulling. The most primitive implement for hulling is the system with wood mortar and pestle or a treadle or watermill. These hulling methods are still used in some of rice growing regions in Asia and Africa. Now mechanical hulling or milling is popular in most of the rice growing countries. The hulled rice grains are then winnowed in order to remove the chaff and bran. Rice with the hulls removed but the bran left on is called “brown rice.” “Milled rice” refers to the rice after removing all hulls, bran layers, and germ. After hulling, the removal of germs or outer coats—the so-called polishing—is necessary by using mechanical hulling or milling for better appearance to meet the market’s need, with sacrifice of the flavor and healthy constituents in rice grains. Rice is generally marked either as polished rice or as coated rice with talc and glucose. Rice grains after polishing contain portions of broken grains that have to be separated and sorted to meet market standards. This separation can be accomplished by passing through a series of sieves or cellular cylinders or trieurs. Some discolored rice grains can be removed by electric sorting.

**Enrichment.** For restoration of vitamins and minerals lost during milling, the enrichment of rice is important for better nutrition. There are two major approaches: powder enrichment and coated kernel enrichment. For preblended powder enrichment, mixes include thiamine, riboflavin, niacin or niacinamide, and ferric orthophosphate (white iron), ferrous sulfate (yellow iron), or reduced iron. This is an easy and less expensive approach for enrichment of rice. But the disadvantages of the powder enrichment are that the nutrients are easily washed off by rinsing, less stability of vitamins and minerals, and their reaction with the food components. An alternative approach is the coated kernel enrichment. This method integrates the powder-blended enrichment with the insoluble food-grade coating. This coating is broken down and the enriched vitamins and minerals are released when the coating reacts with the acid environment of the stomach. This method has the advantage of more efficient use of the enriched vitamins and minerals.

### Global and contemporary issues

In the first quarter of the twenty-first century, another 1.2 billion new rice consumers will be added in Asia. Currently, less than 5 percent of world rice production is traded internationally. Therefore, rice production in Asia must be increased by one third from today’s 320 million tons to 420 million tons, even though rice land is decreasing.

For future rice production, there are also the following challenges: (1) genetic erosion because of the popular adoption of the high-yielding varieties (for example, *javanica* rice germplasm suffered significant losses in Java

and Bali, Indonesia); (2) water pollution by chemical pesticides, herbicides, and air pollution; (3) less cultural management afforded to rice because more rice farmers, especially the young farmers, are moving to work in industry and metropolitan areas, particularly in such countries as China and Japan; and (4) decreasing water resources and increasing land salinity. Global warming might make this trend even more significant.

## RICE AS A FOOD

There are some countries with high annual rice consumption per capita (up to 130–180 kg, equal to 55–80 percent of total caloric source) such as Bangladesh, Cambodia, Indonesia, Laos, Myanmar, Thailand, and Vietnam (Chang 2000). Even in most parts of Africa, rice is a secondary staple food next to cassava, yams, corn, and millet. However, in the following African countries rice is consumed as a staple food: Liberia, Sierra Leone, Guinea, Ivory Coast, Ghana, Madagascar, and part of Nigeria. By comparison with the rice production and consumption in Asian countries, Latin America is often overlooked. However, annual rice consumption in the following countries exceeds more than 32 kg per capita: Brazil, Columbia, Ecuador, and the Dominican Republic.

Rice is the best cereal crop in terms of food energy per production area and is consumed in various forms, including plain rice, noodles, puffed rice, breakfast cereals, cakes, fermented sweet rice, snack foods, beer, wine and vinegar. Rice starch is used as a thickener in baby foods, sauces, and desserts or can be made into sweet syrup. However, most consumption of rice is as cooked rice served simultaneously with vegetable, poultry, beef, seafood, and other dishes. Rice as a comfort food is economical, delicious, nutritious, versatile, easy to prepare, and bland enough to pair with other foods. Rice is convenient to store on shelves in cupboards and pantries.

## Preparation and Consumption

Rice consumption falls into the following three categories: direct food use, processed foods, and brewer's use. Detailed methods and recipes for rice food preparations were described by Bor S. Luh (1991), Sri Owen (1993), Jeffrey Alford and Naomi Duguid (1998), and Bor S. Luh (1999).

**Direct food use.** Rice is easy to prepare, has a soft texture for the human palate and stomach, and has the ability to absorb flavors while retaining its texture. Therefore, rice has gained popularity as "the pasta of the 1990s" in the West. Both the short-grain *japonica* and the long-grain *indica* rice include non-glutinous and glutinous types. Non-glutinous rice is somewhat transparent and is less sticky than glutinous rice when cooked. There are some rice varieties with an attractive aroma, such as basmati. Parboiled rice was originally produced in Asia, but the parboiled rice produced in the United States now, such as by the company Uncle Ben's, is of high quality. Arborio rice has large tan grains with central white dots

and, because of its creamy, chewy texture, can be used to make risotto.

American wild rice is a coarse grass (not a true rice by taxonomy), and now has become more and more popular in the United States and Canada. It is grown in shallow waters and has medium to long grains and a nutty flavor.

Rice is cooked by heating (either boiling or steaming) soaked rice for full gelatinization of the kernels and evaporation of excess water. Generally there are three rice cooking methods: large-amount-of-water method, absorption method, and steaming method. The lot-of-water technique is good for arborio, basmati, or parboiled rice, but not for Thai jasmine or japonica rice with low amylose content, which should be cooked by steaming. Rice cooking methods also include rinsing, boiling, baking, roasting, frying, and pressure-cooking. It is customary to wash rice before cooking to remove dust, husks, insects, and other impurities. American-grown rice does not require washing or rinsing before cooking because these "cleaning" processes further remove nutrients, including vitamins and minerals that were added before packaging by fortification or enrichment.

Juliano (1985) indicated that rice cooking methods vary with different countries. Either uncooked rice or fully cooked rice combines well with other protein-rich foods such as meat, poultry, fish, cheese, and eggs because rice is bland in flavor and carries the flavor of the mixed ingredients. People in the Middle East lightly fry rice before boiling. Americans often add salt, butter, or margarine to soaked rice. People in China, Korea, and Japan add extra water to cook rice into porridge (thick gruel) or congee (thin soup). Rice can be cooked with curries (in India and Malaysia) or sauce (in the Philippines) or combinations of various ingredients, including pork, shrimp, chicken, and vegetables (in China) (Boesch 1967). Steamed rice is preferred in some countries because more vitamins and minerals are retained. Rice can be steamed in a bamboo steamer or, currently, in an electric metal steamer. Steamed rice can be served plain or mixed with other ingredients. Mixed steamed rice also varies among countries. For example, Malaysians steam glutinous rice with mixed meat in a bamboo joint over a fire. Cambodian *kralan* is steamed rice mixed with grated coconut and beans. Iranians steam rice with oil or with butter, and sometimes with yogurt, while rice is cooked with water and oil in Brazil, Chile, Ecuador, Germany, Mexico, and Peru. Some countries, such as France, Korea, Burma, Thailand, Japan, and the Philippines, add rice to cold water for cooking. Presoaking is a common practice in India. Detailed descriptions of recipes from different countries for cooked rice are provided by Virmani (1991). Rice can be kept as long as five days in the refrigerator. The leftover rice is good for stir-frying into egg fried rice with chopped carrots and the like. Rice can also be cooked with certain amounts of water and meat, seafood, vegetables, or other additions in clay pots or

high-pressure metal pots to make thin or thick congee (or *juk*) or gruel (*okayu*, in Japanese).

**Parboiled rice:** Parboiling is popular in India, Sri Lanka, Pakistan, Brazil, the United States, and Italy. Parboiling changes rice starch from the crystalline form to an amorphous form by a series of procedures including cleaning, grading, soaking, steeping, steaming, drying, tempering, milling, color sorting, and finally packaging. It involves the treatment of grains in cold water and then hot water with low pressure. The treated rice can be dried by the steam or sun. Problems of off-color and off-flavor that resulted from conventional parboiling procedures have been overcome by various inventions, such as the H. R. Conversion and Malek Processes (D. H. Grist, 1986). Major advantages of parboiling over ordinary milling include easier dehulling; less breakage in milling; higher retention of nutrients after milling, washing, and cooking; and better resistance to insect and fungus infestation, which makes it possible to store the rice for longer periods of time. Also, parboiled rice gelatinizes the starch and makes better consistency, greater hardness, and better vitreousness of the kernel. The main disadvantages of parboiling include greater rancidity during storage, longer cooking time, greater difficulty in milling, and additional cost (De Datta, 1987).

**Rice-flour products:** Rice flour does not contain gluten and therefore its dough cannot retain gases during baking as wheat flour does. Therefore, rice flour is widely used in making baby foods, breakfast cereals, unbaked biscuits, snack foods, pancakes, and waffles. For example, a composite baking flour, made by adding 10 percent rice flour to wheat flour, is used to make pastry products in Italy.

Rice-flour products are exemplified by the following foods: *yuan zi* (or *tong yuan*) is a popular food in China. It is made from glutinous rice flour and water by adding sweet or savory fillings to the rice dough. The quality of *yuan zi* preparation depends on the amylopectin content, the flour particle size, and the recipe for the fillings. (The higher the amylopectin content, the softer and more sticky the rice flour becomes when the same amount of water is added.) *Yuan zi* is fried with vegetable oil or thoroughly cooked in boiling water and served with sugar or other condiments.

Rice bread is a good substitute for other gluten-containing cereal flour, as some people are allergic to these flours. The medium- and short-grain rice varieties are preferable to the long-grain type for making rice bread. Formulation is important in making rice bread by adjusting the levels of sucrose, yeast, water, nonfat dry milk, and other additives.

**Processed foods.** **Rice noodles:** Rice noodles are called *mi fen* in Chinese, *sen mee* in Thai, and *barusame* in Japanese. *Mi fen* is often produced from non-glutinous rice by soaking, grinding, steaming, kneading, and drying. If dehydrated, it can be stored up to two years. In Thailand,

mung bean is added to rice to make a special rice noodle called *fung-shu* (or *tong-fun*) that is more resistant to texture changes during reconstitution. In Asia, rice noodles are consumed in soups or as snacks. *Mi fen* is served with water, meat or chicken, green vegetables, soy sauce, and other ingredients.

**Rice snacks:** Rice snacks have an attractive taste, flavor, texture, and aroma. They are often made from glutinous rice because of its sticky characteristics and easy expansion into a porous texture. However, non-glutinous rice also can be used for making some rice snacks.

The rice cracker is a typical rice snack. The Japanese soft rice cracker made from glutinous rice is called *arare* or *okaki* in comparison with the less popular and tougher *senbei* (the rice cracker made from non-glutinous rice). The production process involves washing, grinding, steaming, kneading, cooling, pounding, drying, baking, seasoning, cutting, and packing. The production of rice crackers is now developed as a continual process that takes place within 3–4 hours. To add flavors and color to rice crackers, the following ingredients are often added: seaweed, sesame, red peppers, sugar, food pigments, and spices. Moreover, high-quality, refined oil should be used for oil-fried crackers.

Rice fries can even compete with the French fries made from potatoes because rice fries have a crisp exterior crust and fluffy interior. To make rice fries, rice should be fully cooked with butter, salt, and other seasonings.

**Rice cakes:** Rice cakes are popular in China, Japan, and other Asian countries. They can be made either from glutinous or non-glutinous rice by soaking and steaming. Before steaming, various ingredients can be added for more flavor, such as sugar, salt, monosodium glutamate, crushed radish, crushed mung bean (for *lu du gao*, a special cake in China), and crushed taro.

Glutinous or waxy rice is very sticky when cooked and is mainly consumed in northern Burma, northern Thailand, Laos, and Vietnam. It is often used to make rice cakes. However, fermented rice cakes, such as *fakau* in China and *bibingka* in the Philippines, can also be made from non-glutinous rice.

Puffed rice cakes are popular in China and the United States because they are rich in taste, low in calories, and free from cholesterol. To make puffed rice cakes, some minor ingredients, such as sesame seed, millet, and salt, should be added to brown rice.

The Chinese rice cake *zong zi*, the same as *chimaki* in Japan, is made from glutinous rice and soda ash, wrapped in bamboo leaves to form a tetrahedron, bound with string, and served with honey or sugar. There are two main categories of *zong zi*: *chien zong* and *rou zong*. The difference between *chien zong* and *rou zong* is that pork or ham and other ingredients are added to *rou zong* to enrich the flavor and nutritional value. Other ingredients include mushrooms, soy sauce, monosodium glu-

tamate, sugar, black pepper, sherry wine, fried garlic, cooking oil, and shrimp meat.

**Neng gao** or **nian gao** (*mochi* in Japanese) is also a special rice cake for the celebration of the Chinese Lunar New Year. It is produced either from glutinous rice or from nonglutinous rice. The main production procedures involve soaking, steaming, kneading, and packing. For better taste and flavor, *neng gao* is sometimes sweetened with sugar or enriched with lard and cinnamon flour.

In Japan, sushi is a rice cake or roll or cube topped with raw fish or other delicacies and served with wasabi (Japanese horseradish). Fresh raw fish used in sushi include tuna, bonito, shrimp, squid, and shellfish. Vegetables such as cucumber and seasoning gourd also can be put in the middle of the rolls, which are then wrapped with seaweed (*nori*). Sushi usually is served with rice vinegar and soy sauce (*shoyu*).

There are many other types of rice cakes made in Asia. For example, *biko*, *cuchinta* (or *kutsinta*), *puto*, *suman*, and other rice cakes are made in the Philippines.

**Rice puddings:** Rice can be made into creamy puddings by mixing cooked rice with milk and sugar. Indian consumers sweeten rice pudding with palm sugar. Rice puddings were served to the rich during the time of the ancient Romans. Now, rice pudding has become a popular dish for children. A delicious Chinese pudding is the Eight Jewel Rice Pudding, prepared from eight different kinds of fruit and steamed glutinous rice with honey.

**Quick-cooking rice:** The preparation and cooking of conventional rice take about one hour. Now, quick-cooking rice product is popular in developed countries, such as Japan, the United States, and other Western countries. Completely precooked rice requires no further cooking. However, quick-cooking rice often requires five to fifteen minutes for cooking. To produce quick-cooking rice, rice should be precooked by gelatinizing the rice starch in water and/or steam and then dried. Quick-cooking rice mainly is produced by the soak-boil-steam-dry, freeze-thaw-drying, expansion-pre-gelatinization, and gun puffing methods.

**Canned and frozen rice:** For convenience of consumption, canned and frozen rice are produced in Japan, Korea, the United States, and other countries. After pre-cooking, canned rice is sold by wet pack and dry pack. The preparation of frozen cooked rice includes soaking, draining, steaming, boiling, and freezing. To serve the frozen cooked rice, microwave heating is a common practice. Frozen rice also can be made into freeze-dried rice by sublimation under high vacuum. This rice has a long storage life of one to two years.

**Rice breakfast cereals:** Some rice breakfast cereals require cooking before eating, while others can be eaten directly. They commonly are fortified with minerals and heat-stable vitamins, such as niacin, riboflavin, and pyridoxine. The ready-to-eat breakfast cereals include oven-

puffed, gun-puffed, extruded, and shredded rice. Oven-puffed rice is made from short-grain rice with sugar and salt by cooking, drying, tempering, enriching, and packaging. Gun puffing is a traditional method and is still practiced in some Asian countries, such as China. The procedure consists of heating, cooking with high pressure in a sealed chamber or gun, and suddenly releasing the high pressure. Because of the lack of continuity in processing, gun puffing is less popular in developed countries. Instead, making extruded rice has high and continuous production rates, great versatility in product shape, and ease of controlling product density. The production of extruded rice can be accomplished by extruding superheated and pressurized doughs. Shredded rice is produced by washing, cooking, drying, tempering, shredding, fortifying, and packing.

**Baby foods:** Rice has highly digestible energy, net protein utilization, and low crude fiber content. Therefore, it is suitable for baby food. Although baby foods can be in the form of rice flour or granulated rice, precooked infant rice cereal is the most common use of rice for baby food. The key to making this type of cereal is ensuring the ease of reconstitution with milk or formula without forming lumps. The starch is converted from crystalline to amorphous form by the addition of amylase, which breaks down starch into dextrin and oligosaccharides. Ingredients in this baby food include rice flour, rice polishings, sugar, dibasic calcium phosphate, glycerol monostearate (emulsifier), rice oil, thiamine, riboflavin, and niacin or niacinamide. Sometimes, fruit is added to these precooked rice cereals.

**Rice-bran products:** Rice bran can be sprinkled on a dinner salad or used as a major ingredient of ready-to-eat cereals, baked products, pasta, and other foods. Like oat bran, rice bran has high-quality protein, laxative properties, and dietary fiber components. Rice bran can lower serum cholesterol in humans and reduce the risk of cardiovascular disease and colon cancer. The bran also contains most of the vitamins in the rice kernel, including 78 percent of its thiamine, 47 percent of its riboflavin, and 67 percent of its niacin. The major carbohydrates in the rice bran are cellulose, hemicelluloses (or pentosans), and starch.

Rice bran has hydrolytic rancidity after milling. Therefore, the following treatments are necessary before it is processed as a food: indigenous lipase inactivation by parboiling, or moisture-added or dry extrusion, or other alternative methods.

Rice bran has 16–32 percent oil, including palmitic, oleic, linoleic, and other fatty acids. Therefore, rice bran can be processed into rice oil of the highest quality in terms of cooking quality, shelf life, and fatty acid composition. Oil extraction can be carried out with a variety of solvents using a hydraulic press or specially designed extractors before refining by dewaxing, degumming, neutralization, bleaching, winterization, and deodorization.

Women processing rice at a cooperative in Mozambique. © ADRIAN ARBIB/CORBIS.

After these steps, rice bran oil has greater stability than any other vegetable oil. Rice oil also can be used in cosmetics and paints.

**Brewer's use.** Rice alcohols include rice beer and rice wine, which is usually served at weddings and other annual rituals. Rice wine is distilled spirits having about 20 percent alcohol content. China has a long history of making rice wine, such as *wang tsiu* ("Shao Shing rice wine"). Nepal also has a slightly sweet rice wine called *nigar*. Other rice wines include *tapuy* in the Philippines, *mukhuli* in Korea, *lao rong* in Thailand, and *moonshine* rice wine and *ba-xi de* (a glutinous rice wine) in Vietnam.

In China, *tian jiu niang* is a popular mixture of rice grains, alcohol, lactic acid, and sugar. It is made from steamed glutinous rice. *Jiu qu*, containing *Rhizopus*, *Mucor*, *Monilia*, *Aspergillus*, and in some cases, yeast or bacteria, is used to ferment the steamed rice.

Sake is a brewed alcoholic beverage having 14–16 percent alcohol content. The production of sake began in third century Japan. Sake is made from highly-polished rice, water, *koje*, and sake's yeast. *Koje* are microbes similar to those used in the production of cheese, *shoyu* (soy sauce), and miso (soy bean paste). *Sakamai* or *shinpakumai* rice should be selected for sake production for better quality because of its high starch content and its large and soft grain. Another important ingredient is the spring water, which leads to rich flavor.

The processes to make sake can be summarized as the following: (1) saccharification: conversion of the starch in cooked rice into glucose with *koje* or *koji*; (2) fermentation: conversion of the rice sugar into alcohol by sake's yeast. Fermentation for 20–25 days (three or four times longer than the fermentation in normal wine production) produces a balanced taste and fresh flavor from a wide variety of amino acids and low alcohol content (8–15 percent); and (3) further steps including filtration, setting, heating, aging, and bottling. Sake should be preserved in a cool and dark place without any exposure to light and open air.

### Nutritive, Health-related, and Psychopharmacological Value

Rice ranks high among the most nutritious foods available because brown rice provides high levels of fiber, complex carbohydrates, certain B vitamins, vitamin E, lysine, calcium, iron, and phosphorus. Furthermore, many fewer people are allergic to rice than to wheat or other cereals. Rice can be included in a weight-loss diet because it has no cholesterol, a trace of fat, and about 160 calories per cooked cup.

Recent studies have indicated that rice hull or bran contains antioxidants such as isovitexin (a C-glycosyl flavonoid), and it has been demonstrated that rice bran oil can lower both the total and the low-density lipoprotein cholesterol in non-human primates (Nicolosi et al., 1990). Some health problems, such as beriberi (thiamin deficiency), growth retardation, marasmus, and vitamin A deficiency, can result from consumption of only white rice, from which a portion of the proteins and most of the fat, vitamins, and minerals are removed. Rice bran (*tiki-tiki*) is used to cure beriberi in the Philippines.

Since rice is low in sodium and fat and free of cholesterol, it can help relieve mental depression. Rice starch can substitute for glucose in an oral rehydration solution for infants suffering from diarrhea caused by a spleen-pancreas deficiency (Juliano 1985). Rice oil is believed to reduce the likelihood of ischemic heart disease.

Although not scientifically proven, rice is believed to have medicinal uses. Powdered rice is used to treat certain skin ailments, and boiled rice "greens" are used as an eye lotion in Malaysia. A thick paste made from rice grains and water is used in India for massage for curing arthritic pain. The Chinese believe that rice can increase appetite and cure indigestion. Rice water (a decoction of rice) is prescribed as an ointment for skin inflammation. Glutinous rice is believed to strengthen the kidneys, spleen-pancreas, and stomach because of its easier digestion compared to regular rice. The Chinese also believe that rice mixed with honey butter and water can build energy and blood and counter emaciation and other disorders (Wood 1999).

### RICE AS A SUPERFOOD

Widely adapted to diverse environments, rice is an important part of culture, traditions, and subsistence in some countries, especially those in Asia. There is a wealth of literature on the rituals and traditions of rice consumption throughout the world (Virmani, 1991; Piper, 1993; Newman, 1999).

### Languages and Symbolism

In Asian languages, daily or important events are expressed in terms of rice. In many Asian countries, such as Thailand (*tarn kao*), Bali (*ngajengang*), Laos PDR, and Bangladeshi, the phrase for eating rice is synonymous with eating food (Williams, 1996). More directly, Chinese and Japanese people refer to breakfast, lunch, and dinner, as morning rice, afternoon rice or noon rice, and evening rice, respectively. Chinese say, in addition to "Happy New Year," "May your rice never burn!" at the beginning of the Chinese Lunar New Year. A common daily greeting in China, Thailand, and Bangladesh is "Have you eaten rice today?" instead of "How are you?" A Japanese proverb says "a meal without rice is no meal," just as the Chinese think that if their friends who are invited to dinner do not eat rice, they have eaten nothing. Rice is so important in Malagasy that the Malagasy word for rice is used as a unit of measurement for time

and distance, and in expressions, proverbs, and riddles. Malagasy people refer to “friendship” as rice and water, and to “perfection” as rice with milk mixed with honey.

Rice generally is a positive symbol. In ancient Japan, rice was considered most important next to the emperor. Any wasting of rice was not allowed. In the Japanese feudal period, the chiefs were ranked based on their rice yield. In some Asian countries, such as the Philippines, rice cakes are used as ceremonial foods because they mean long life, happiness, abundance, prosperity, and good fortune. Koreans also believe that a baby will become rich if the child chooses rice from among all the objects put on the table in a “choosing” ceremony.

Rice has other meanings. In Chinese culture, death is symbolized by sticking chopsticks into a mound of rice. Chopsticks are placed on the rice bowl at one end as a memorial of the dead at festivals or important family gatherings. In addition, rice grain symbolizes devotion, affection, generosity, and respect in Nepal, and it is symbolic of a man’s body to Thai villagers.

### Cultural Preferences

Preferences for rice vary from culture to culture, and from person to person. Most of the major rice-consuming countries eat plain or mixed rice prepared from regular or parboiled rice. Korean rice consumers prefer new rice because of its fresh taste and white color. Laotians prefer the sticky, short-grain varieties and often cook them plainly. In Pakistan, a large quantity of rice is consumed typically as biryani, which is cooked in a meat sauce with other ingredients. In Thailand, *khao tom* (a soft soupy rice gruel) is served as breakfast with other dishes, but the most popular rice dishes include garlic rice, saffron rice, rice colored with coconut milk, and fried rice with meat and tomato ketchup or fish paste. In the Middle East, sautéed rice with vegetables, fruits, and nuts is popular. People in Central Asia consume rice as a festival food and eat rice prepared as rice pilaf. For example, Iranians eat boiled long-grain rice with grilled meat and soup or tea. Most African people also eat plain boiled rice with soup, meat, and seafood. But in some regions in Vietnam, mixing rice with several other dishes is socially unacceptable. India has the following common preparations for rice meals: plain boiled rice, *khichri* (rice cooked with mung beans), *pullao* (fried rice), and *kheer* (rice pudding). Parboiled rice is also important in India. In the Philippines, rice is served at each meal in the form of steamed rice with meat or seafood. In Indonesia, rice is eaten all the time, either as a main dish or as a side dish with other vegetables, fruits, or meat. Many Indonesian consumers eat red rice and unpolished rice. *Ketupat lontong* (rice rolled and steamed in banana leaves), *nasi goreng* (fried rice sprinkled with saffron or turmeric), and *nasi tumpeng* (a cone of white rice garnished with red, black, and yellow food) are specialty rice foods in Indonesia. Rice can be prepared or served in banana or palm leaves in Malaysia. In Japan, non-glutinous rice is used

in daily meals, together with pickles. Pot rice, prepared with rice, soy sauce, fish sauce, and sometimes seafood, meat, or vegetables and mushrooms, has become a popular rice food in Japan. In Korea, the daily meal consists of steamed rice and vegetables, fish, meat, soup, and *kimchi*. A popular Korean dish is *pah jook* (a combination of rice and beans). Pakistanis generally eat aromatic rice, either plain or cooked with meat.

Cultural preferences for different rice varieties also exist. Rice consumers in Peru prefer long-grain and non-glutinous rice prepared with oil, garlic, and salt. Brazilians like soft, non-glutinous, and aromatic rice prepared in various ways. In Australia, rice consumption reflects an increase in the influence of Asian culture, and people generally prefer long-grain rice despite domestic production of short-grain *japonica* rice.

Rice is served as other forms of foods. Vietnamese usually steam soft rice with extra water and make rice noodles or pancakes. For their breakfast, they usually eat a large bowl of noodle soup, sometimes with sticky rice gruel. In the south of India, the common rice foods include steamed rice muffins and rice pancakes for breakfast. In Myanmar, favorite dishes include *mohinga* (rice noodles served with fish, eggs, and other ingredients), rice cooked with coconut milk, and rice with hot and sweet vegetable soup. *Nasi dagang* is a traditional Malaysian food made from unpolished glutinous rice with coconut milk and other ingredients. In Thailand, rice is also consumed as rice balls, rice cakes, rice pudding, and rice noodles.

Rice is sometimes indirectly consumed. In the Middle East, rice is used as a stuffing in other foods. Iraqis prefer short-grain rice in the form of plain boiled rice or rice stuffed in peppers or in chicken or turkey. In ancient Japan the rice wine sake was consumed primarily in the imperial court, larger temples, and shrines. Today, it is served at traditional ceremonies in Japan. In South and North America, rice is a supplemental food in Mexico, Peru, and Brazil. Rice is consumed as rice noodles, fried rice, rice cakes, and rice pudding (in Mexico). European people prefer rice cakes and rice puddings made from long-grain and aromatic rice.

Cooked rice can be served and eaten in different ways. Bowls and chopsticks are used for eating rice and other foods in China and Japan. But flat plates, spoons, and forks are used in Thailand instead. In India, rice is served on a banana leaf, a plate, or a metal tray, and eaten with the hands.

### Rituals

There are many rituals for each stage in the production of rice. When opening a water channel, holy water from central lakes is sprinkled onto the field and the priests from the mountain temple make blessings. After sowing the seeds, a dance feast is held in Borneo, in which masks are worn to frighten away the rice evil spirits. Rice seed

development is considered as if it were a pregnancy. Therefore, there are birth rituals in which people sing to the baby rice. Harvest is celebrated with dances as a Thai tradition. During rice harvest in Bangladesh, *pithas* (a popular dish) are made from new rice flour. The Iban farmers of Malaysia will whisper an apology or make amends with a special ritual for any rice grain wasted.

### Customary Beliefs

The origin of rice is believed by Malaysian people to be associated with the sky (Sri Owen, 1993). It is believed in some countries that rice is holy and therefore should be well treated, protected, and honored. For example, men are usually not allowed to carry rice to the granary and cook it. Women also should show deference to rice. They should enter the rice granary at night or noon when rice spirits are sleeping, and be properly dressed without making noises by talking or chewing. Their breasts should be covered and they should enter the granary with right foot first. In China and Singapore, a good job is symbolized by an iron rice bowl, and a broken rice bowl means “out of a job.” It also is considered bad luck to upset a rice bowl.

### Festivals and Holidays

Rice is an important ritual food to celebrate the New Year. To celebrate the Japanese New Year, *Oshogatsu*, *mochi* (a glutinous rice cake) is prepared by toasting over a fire (a similar tradition to the current practice in central China) and served to begin the year on the “right foot.” A special spiced rice wine, *tosu*, is used for the celebration of the New Year. The New Year ends with special rice porridge. Similarly, to celebrate the Chinese New Year, *nieu koay* (a sweet and sticky rice cake) is offered to the deities in Malaysia, and *Tet* (the Lunar New Year) is celebrated with glutinous rice cakes in Vietnam. *Nien gao* (glutinous rice cakes of different shapes and colors), sounding like “going high” in Chinese, is served in China for the celebration of the Chinese Lunar New Year as a good luck symbol. To celebrate the Lunar New Year in Thailand, sticky rice cakes are prepared with mortar and pestle and cooked in the fire until a golden brown color is obtained.

Rice plays an important role in other festivals or ceremonies. In Sri Lanka, for the first day of every month and for festivals, *karibath* is served with milk and curries. On May 15 every year, the small town of Lucban in Quezon Province, the Philippines, celebrates the *Pabiyas* (precious offerings) Festival by decorating the outside of the houses with *pabiyas* made of rice flour paste. For the Chinese *Duan Wu* (Dragon Boat) Festival on the fifth of the fifth lunar month, *zong zi* (triangular and leaf-wrapped rice cakes) is prepared and dropped into the river or sea for appeasing the soul of an ancient minister, *Qu Yuan*, before the boat races. *Zong zi* is often eaten before the family-union feasts for celebration of the *Duan Wu* festival. In the Philippines, *pagdidiwata* (a thanksgiving festival) is celebrated by sharing rice wine with spirits. Rice

is involved in other ceremonies or festivals in India, including naming ceremonies (*namkaran*) and birthday celebrations. Rice also is important in India during the *Bhai Dhoj* (sister-brother day), *Diwali* (festival of light), *Makar Sakranti* (January 13), and *Pongal* festivals.

In Thailand, the Royal Plowing Ceremony has been a great event in front of the Grand Palace in Bangkok for more than 700 years. In the ceremony, the *Phraya Raek Na* (Lord of the Festival) performs a rite to predict the weather during the coming season, plows the field with a pair of ceremonial bulls, and scatters the rice seeds into the field with the help of the four *Nang Thepis* (consecrated women). People will rush to the field to pick up the sacred rice grain to take home. In the past, the traditional dance *Rabam Mae Posop* was performed to honor the rice goddess. Cambodia also has a similar royal plowing ceremony to mark the beginning of the rice-growing season.

### Social Behavior

Rice (scented rice, colored rice, or rice alcohol) also can be served to family and friends to cement relationships or to enhance status. These ceremonies include the following situations: at marriage, at births, before building a house, before a major hunt, and before the start of a new season.

Rice is popularly used in wedding ceremonies because it is the symbol of life and fertility. In Indian wedding ceremonies, a handful of rice is tied to the corner of the sari of the bride when newlyweds take their vows. Upon arrival at the groom’s house, she will step on a pan full of rice and the rice spilled out of the pan will be kept by the family for remembrance. In India, Sumatra, the United Kingdom, and some parts of the United States, rice grains are showered on the newly wedded couple for good luck and a fruitful marriage. It is suggested that this tradition might originate from China (Boesch, 1967). In wedding ceremonies in Myanmar, colored rice grains are showered on relatives and friends, as well as on the newlyweds, for good wishes. During Japanese weddings, the newly wedded bride and groom are required to take three sips of sake from each other’s cup. Rice grains or rice flour are served during wedding ceremonies. In *pokok nasi* (a wedding ceremonial offering in Malaysia), glutinous rice is used as bedding for the artificial tree made of boiled eggs, leaves, and stems. In Bangladesh, *biryani*, a spicy dish consisting of rice and goat’s meat, is served at wedding receptions in the urban areas. Special rice cakes called *nakshi pithas* also are prepared for wedding ceremonies. In the later part of wedding ceremonies in Sumatra, the newlyweds will “pull chicken from yellow rice” by custom.

Rice is an essential ingredient of offerings at birth celebrations. In Perak, Malaysia, rice is traditionally used to present the newborn to the spirit of the river by making offerings (rice packets, betel, and eggs) at the river side; rice dust and parched and yellow rice are sprinkled and scattered on the water. In Korea, *Yakbap*, glutinous

rice steamed with nuts and honey, is served on festive occasions, such as birthdays and New Year's. Rice cakes or rice meals and *bobju*-wine (a rice wine) are served during wedding ceremonies and the celebration of births. The sharing of rice cakes among one hundred people symbolizes good luck and long life for the baby.

Rice can be found in other significant events. Special sweet and mild sake is used to celebrate *Hinamatsuri* (the Japanese Girl's Day). Rice paste is involved in purification ceremonies in Malaysia and other countries.

### Spiritual Beliefs

There are many origin myths and much folklore about rice (Sri Owen, 1993). It is believed that there are many gods or goddesses related to rice. The gods or goddesses gave rice to humans and taught them how to grow rice. Religious use of rice takes place in India, China, Thailand, Indonesia, Sri Lanka, and Malaysia. In Asia, the rice spirit is female and often a mother figure. Cambodian rural villagers believe that *Yiey Tep* (a female guardian spirit) stays in the rice field. Therefore, they offer food (often sweet rice porridge) at the corners of rice fields (Solieng Mak, 1998). The Chinese believe that, in order to save hungry people, the goddess Guan Yin squeezed her breast so hard that her milk and blood went into the rice grains. That is why we have both white and red rice. In the northern Himalayas, the goddess *Pavarti* is believed to be the first to have grown rice. Indians worship rice as *Lakshmi*, the Hindu goddess of wealth. For Indians in Malaysia, rice flour is used to decorate the entrances of houses to welcome Lord Krishna and the goddess *Lakshmi* at *Deepavali* (the Festival of Lights). Indonesian people perform rituals to honor the goddess *Dewi Sri*. The "first fruits ritual" occurs before the harvest, in which rice dolls symbolizing *Dewi Sri* and her partners are made and placed in the rice granary or at home to ensure a bumper harvest. The Balinese honor *Dewi Sri* by offering dyed rice paste at celebrations. The *jaja*, which is made from colored rice paste of different shapes and prepared in different ways, is used for decorating offerings of fruits and flowers at merry or solemn Balinese ceremonies or festivals. At many other festivals, cooked and colored rice cakes are offered, decorated with flowers and palm leaves. The Balinese believe that *Indra* (Lord of the Heavens) taught men how to grow rice and rice is the soul of man. When the Balinese plant the first rice seedlings in the field, a special planting pattern is followed for the first nine seedlings after offerings are made to *Dewi Sri* (the goddess of rice). Multicolored cones of cooked rice are used for recalling the *nawa sanga* (rose of the winds) (Piper, 1993). In Japan, it is said that the sun goddess *Amaterasu-Omi-Kami* first grew rice in the field of heaven, and Prince Ninigi brought it for human culture. Japanese classic records also indicated that rice came from the eyes of the food goddess *Ohegetsu-hime*. The goddess for rice is *Bok Sri* in Java. The union of *Bok Sri* with *Djaka Sudana* (the male rice spirit) is celebrated by people working in the nearby fields. In Thailand, the rice

goddess or rice mother, *Mae Posop*, is worshiped and believed to bring good harvest. Therefore, no men, loud noises, or talk of death or demons are permitted before harvest since *Mae Posop* is shy and easily frightened; miscarriage of her pregnancy during harvest time might occur. *Khao Chae* in Thailand also originated from the celebration of the first day in the lunar calendar when the Mon people offered *Kao Songkran* (*Songkran* rice), later *Khao Chae* modified with ease to be soaked (*chae*) in water, to the female guardian spirit of the New Year. The Rungao people in Vietnam believe that the shadow on the moon is the goddess heaping rice.

Other religious beliefs include the following: *Pulang Gana* is the spirit for rice growth in the beliefs of the Iban people. In Nepal, *tika*, the holy mark made from rice grains and yogurt, is put on the forehead of youngsters by elders for blessings during religious occasions. Similarly, at the *Durga Pooja* festival, rice sprouts are offered to youngsters as good blessings from the goddess *Durga*.

People believe that rice spirits are involved in rice production. For the Iban, *padi pun* (the sacred rice) is protected by prohibitions, acts of respect, and deference. For example, it is not handled by men and never sold to others. It is harvested last after harvesting other rice without any break in the path of harvesting. Sometimes, the bamboo pole is used as a bridge to the gap between harvesting locations with singing, prayers, and offerings so that the spirits from all harvested rice eventually come to the *padi pun*. When the Iban people harvest rice, they use a concealed knife in order not to offend or scare away the rice soul. The Brou people in Cambodia have a similar tradition when clearing the forests for growing rice. They show their respect to the local *arak* (minor spirits having a particular location) with offerings and ceremonial articles such as a knife, axe, banana shoot, and chick legs on which chicken blood is poured. When harvesting, beer and chicken are placed in the rice field as thanks. Both Iban and Brou people pray for an increase in the quantity of rice in the granary.

Jiming Li

**ROASTING.** Roasting is a dry-heat method of cooking whereby meat or poultry is cooked on a spit over a fire or in a pan in an oven. Roasting began in prehistoric time when the first human stuck a piece of meat on a stick and held it over a fire. Spit-roasting fowl and game was common in ancient societies. In the Middle Ages, hunting was a prime occupation of the noble classes, and the game was usually roasted on a spit. Suckling pigs were also candidates for the spit. Beef, however, was not; it was considered “vulgar” because cattle did not have to be hunted. Not until the seventeenth century did roast beef become widely accepted in Europe.

Roasting, perhaps because it requires prodigious amounts of fuel and large pieces of meat, has always been considered the most prestigious form of cooking. The world’s largest and oldest gastronomic society, the *Confrérie de la Chaîne des Rôtisseurs* (The Brotherhood of the Chain of the Roasters), was founded in Paris in 1248 by masters in the art of roasting geese (called “rotisseurs”). The object of the Guild was to perpetuate the standards of quality befitting the royal table under Louis IX, King of France. The king loved his roast for the same reason people still love roasted meat: roasting develops and improves the flavor, color, and aroma of food. Properly roasted meat is tender, delicious, appetizing, and easier to digest than meat cooked by other methods.

The roasting method is one of the simplest ways to cook fine cuts of prime beef, lamb, pork, and veal, but, as any culinary student can tell you, simplicity in the field of culinary arts can be tricky. In cooking, as in all of the arts, simplicity is the sign of perfection. Roasting is often the method of choice because it yields a tender pink interior and crisp browned exterior through prolonged oven cooking. Before beginning the oven-cooking phase of the roasting process, the meat must be trimmed, tied, seasoned, and, if possible, seared.

A roast begins as a piece of meat either on the bone or with the bone removed. A roast can range in size from a small pork loin, boned and rolled, that can feed four, to a beef round on the bone that can serve up to one hundred people. Such large, or primal, cuts are usually cooked by the roasting or rotisserie method. As a verb, “to roast” means to oven-cook food in an uncovered pan, over indirect heat. A “rotisserie,” the noun, cooks food by slowly rotating it over direct heat.

A rotisserie contains a spit fitted with a pair of prongs that slides along its length. Food (usually meat) is impaled on the spit and the prongs are screwed tightly into place to hold the food securely. Roasting and rotisserie cooking produce the best results with reasonably tender pieces of meat or poultry. Tougher pieces of meat usually require moist cooking methods such as braising or pot-roasting. When time allows, less tender but larger,

**TABLE 1****Roasting times and temperatures (temperature in degrees Fahrenheit)**

Food	Oven temperature	Roasting time	Doneness and temperature
Beef: Whole tenderloin (4 lbs.)	400	35–45 minutes	Rare 120–130; medium rare 130–140
Top loin (4½ lbs.)	425 for 15 minutes, then 350	1¼–1½ hrs.	Rare 120–130; medium rare 130–140
Prime Rib(5-rib, 12-lb. roast)	325	5-rib (11–13 lbs.): 2¼–2¾ hrs. 3-rib (7–8½ lbs.): 1½–1¾ hrs.	Rare, 120–130; medium rare 130–140
Leg of lamb (8 lbs.)	350	1hr.–1½ hrs.	Rare 120–130; medium rare 130; medium 140
Pork loin boneless (4 lbs.)	350	2¼–2½ hrs.	Cook to 160
Chicken (4–7 lbs.)	400	1 hr.–1¾ hrs.	Cook to 175 in thigh
Turkey (10–25 lbs.)	325	10–12 minutes per lb. unstuffed; 12–15 minutes per lb. stuffed	Cook to 175– 180 in thigh

fatty meat joints can also be cooked rotisserie style to achieve the same results as tenderer cuts.

The standard temperature for cooking roasts is 350°F, but the ideal temperature (or set point) can vary plus or minus 50°F, depending on the cut. Technically, the lower the heat of the oven, the better the final roasted product will be. At a lower temperature, the meat takes longer to cook but produces more flavor, retains more moisture, and shrinks less. In the process, the crispy outer character associated with the classic roast is somewhat diminished. When roasting meat at a temperature below 200°F, most professionals rely on Altra-Sham® cooking technology, a method that combines a constant, precise low temperature with relatively high humidity. At these same low temperatures, other wood-fired heat source methods of roasting—barbecuing, pit-roasting, and smoking—also produce desirable results.

Barbecuing is a roasting method of cooking. Food is covered and slowly cooked in an open pit or on a spit, using hot coals or hardwood as a heat source. The food is basted, usually with a highly seasoned sauce (with a vinegar or sweet tomato base) to keep it moist. North Carolina and Kansas City are two of the most famous U.S. spots for barbecue.

This roasting apparatus for chicken was devised in England in the early nineteenth century for use in hotels. This scene dates from about 1850. The rotisserie turns as the cook turns the crank. The reed screen on the left suggests that this was extremely hot work. ROUGHWOOD COLLECTION.

When meat is cooked slowly in a large hole in the ground, it is pit-roasted (more precisely, “pit-braised”). A hardwood fire is built in a pit and the wood is allowed to burn until the pit is partly filled with burning coals. The coals are then completely sealed with gravel and sand. Sometimes the meat is wrapped in fresh leaves, especially whole carcasses like pig, lamb, and goat. The wrapped meat is placed on the sand and then completely covered with earth, which holds in the heat and steam. Cooking times can vary from five to ten hours, depending on the size and thickness of the meat and how fast the coals are burning.

Smoke-roasting, also called hot smoke-roasting, is generally considered a restaurant application. Specialized ovens that apply constant heat and variable smoke intensity from a built-in smoker compartment are used to produce hot-smoked food. This application of heat and wood smoke are ideal for roasting meat, poultry, and fish because the food cooks at a low temperature under static conditions and there are no drying drafts of air moving through the smoker. The result is a tender, moist roast with consistent smoke flavor.

Once the internal temperature for a roast has been determined, the cook prepares the roast itself. The typical procedure for the roasting method is to place the prepared meat (trimmed, seasoned, and seared) into the oven in a roasting pan on a roasting rack. A roasting rack is required for a successful roast because it holds the roast above the pan in which it is roasting. This prevents the meat from cooking in its drippings and allows adequate air circulation for even cooking and browning.

Meat is roasted until a meat thermometer (inserted in the roast) indicates that its ideal internal temperature has been reached. The ideal temperature depends on the type of animal, the type of roast (bone-in or tied), and the cut of meat. There are many ways to tie a roast using either hand-trussing or butcher-wrapping. Roasts are tied for two reasons: to keep the roast in an aesthetically pleasing round shape or to hold stuffing inside of it. After the meat has rested, usually about fifteen minutes, the string can be removed from the exterior of the roast.

During the process of cooking, as meat achieves its ideal internal temperature, many chemical changes occur

## HOW TO ROAST

Roast beef, pork, and poultry are among the most satisfying and impressive dishes the home cook can create, especially for family meals and festive occasions. Roasting is most successful when used with foods with some moisture or fat content. Drier cuts should have some fat added to keep them moist in cooking.

Essential to the appeal of roasting is the fact that it produces a tasty, crunchy crust on the surface of the food. Commonly known as browning, this phenomenon is known to food science as the Maillard reaction, after Louis Camille Maillard, the French chemist who first described the process in 1912. In a Maillard reaction, the heat of cooking causes protein components and natural sugars in the food to break down, combine in complex ways, and produce a brown pigment (technically called “melanoidin”), and the result is a crust that usually tastes rather sweet. The process can be magnified by the cook with the addition of more sugar, such as the glucose in corn syrup, or protein, such as butter.

Meat that is to be roasted should be allowed to sit at room temperature for an hour or two, depending on the size of the roast, in order to let the interior lose its refrigerator chill. (This step is not as important with poultry because the center of a chicken or turkey is hollow, whereas a meat roast is solid.) Allowing a meat roast to sit out for a time should not present a food safety hazard unless the kitchen is very warm; for added safety, the cook might sear the meat to kill any surface bacteria.

There are several ways the cook can be sure to produce a delicious, juicy roast. The roasting pan should not be covered. A covered pan traps the moisture escaping from the meat and surrounds the meat with steam, producing a mushy rather than crisp exterior and a flabby taste. In order to avoid losing the natural juices of the meat, the meat should not be pierced with a fork nor should it be salted before or during cooking. The one exception to the rule against piercing the meat is that a meat thermometer can be used to check for doneness. (See accompanying table for recommended temperatures.) Insert the thermometer before the roast goes into the oven and leave it in during cooking. Measure the temperature in the center of the roast, not touching bone (since bone conducts heat better than muscle and will give a higher reading). Be sure to remove the roast when it reaches a point ten to fifteen degrees below the target temperature since the temperature will continue to rise after the roast is removed from the oven. Allow the roast to “rest” for fifteen to twenty-five minutes (depending on size) after removing it from the oven because heat causes the proteins of the meat to coagulate and give up their

juice; if the meat is carved as soon as it is out of the oven, the juice will rush out, leaving much of the meat rather dry. If the roast is allowed to rest, the meat relaxes and much of the moisture is reabsorbed, allowing for juicy sliced meat.

Meat classified as “Prime” by the U.S. Department of Agriculture has more flecks of fat in the muscle than the next-best grade, “Choice.” Even leaner and tougher is “Select.” Prime meat is hard to find in most supermarkets since it is more expensive and generally sold to the restaurant trade. Choice cuts will roast well, but Select cuts should be cooked with a moist-heat method.

Many different foods are suitable for roasting. Meat made from the rib, short loin, and sirloin cuts make the best beef roasts since they are the tenderest parts of the animal and do well in the dry heat of the oven. Beef cuts ideal for roasting include the tenderloin, standing rib, rolled (boneless) rib, rib-eye, strip loin, sirloin, beef round, and eye of round. Cuts that are both tender and relatively small, such as the tenderloin or rib-eye, can be cooked at high temperatures (400°F) to achieve a well-browned exterior and juicy, tender interior. Larger cuts, such as “prime rib” (standing rib roast) need a lower temperature (250°F to 350°F) to prevent the exterior from overcooking before the interior reaches the desired state of doneness.

Various cuts from pork loin are suitable for roasting, including the tenderloin, top loin roast, crown roast, and rib roast. The whole ham or portion (shank or butt) is a classic roasted dish.

Leg of lamb is considered by some connoisseurs to be the most magnificent cut of meat available for roasting. It can be roasted on the bone; if the leg is deboned, it can be rolled for roasting.

Whole chickens and turkeys are easily roasted, the only challenge being to keep the white meat of a large bird moist until the dark meat, which cooks more slowly, is done. Poultry parts, such as legs or breasts, that are cooked in the oven are said to be “baked,” while the whole bird is “roasted.” Duck and goose can also be roasted, although the fat content, especially with goose, is considerably higher than that of chicken or turkey and the cook will likely find a large amount of grease in the pan.

In the vegetable world, the most commonly roasted items are the potato and sweet potato. In a reversal of the terminology used for poultry, a whole potato is said to be “baked” while potatoes cut up and put in a dish are said to be “roasted.”

*Richard L. Lobb*

that affect its appearance, taste, and texture, including shrinkage, browning, and flavor development. The first effect of roasting is that muscle proteins shrink and moisture is lost. As meat is heated, the muscle proteins coagulate and shrink, squeezing out water. The longer meat is cooked, the more water is forced out. This is why “dry” and “overcooked” have become synonymous. The loss of juices through drip, evaporation, and cooking time, along with the intramuscular fat or marbling content, determine the meat’s juiciness, amount of shrinkage, and, thus, the final cooked weight or portion yield. An accurate internal meat thermometer is an essential piece of equipment for roasting because overcooking produces meat with so little remaining moisture that it is dry and tough.

Heat also affects the internal pigmentation of meat and changes its color. In beef, for example, the red color of uncooked beef changes to light pink, then to brownish-gray as the internal temperature increases from 125°F to 165°F. During long, slow cooking, most connective tissue softens, and collagen (fibrous protein) gelatinizes. Heat also causes fat to melt, and slightly browning fat develops flavor.

It is a myth that searing meat seals in the juices during roasting. Searing or browning the outer, lean surface of meat, usually at a fairly high temperature, does develop flavor and color as a result of Maillard reactions. It is an important step in several dry-cooking methods, including roasting, in order to produce a tasty outcome. When roasting meat, sear it to a good brown color to improve appearance and flavor, remembering that overcooked lean meat will be dry, and therefore not as good to eat as properly cooked lean meat, which is succulent and juicy. Two solutions are available to the cook. One is to bard meat with fat (cover it with strips of fat, usually pork fatback), an outdated practice but one still taught in cooking schools, or to add a fat cap or caul fat wrapping to lean meat. The rule of thumb is to use caul fat on fowl and bard lean roasts before roasting.

**ROME AND THE ROMAN EMPIRE.** Roman gastronomy, or gluttony, impresses all who read the Latin and Greek literature composed under the great Mediterranean empire of the first four centuries C.E. Feasting was a central feature of Roman society. The cuisine of Rome, much influenced by ancient Greece and the Near East, is the direct ancestor of the national cuisines of most of western Europe.

Ancient texts form one of the source materials for reconstructing Roman food behavior. These texts include scientific and technical writings (such as the earliest surviving recipe book, *Apicius*, probably compiled in the fourth century C.E.) as well as lively depictions of food, wine, and banquets in classical Latin prose and poetry. Archaeology is an equally important source of information on this topic. Notable in this context are the finds at Pompeii, the Italian city buried in 79 C.E. by the disastrous eruption of Mount Vesuvius.

#### Historical Outline

Rome was said to have been founded by Romulus and Remus in 753 B.C.E. on the banks of the Tiber in central Italy. It was a country town whose power gradually grew until it was the center of a world empire. In the third and second centuries B.C.E., Rome fought and defeated the Carthaginians of north Africa, a victory that opened the way to Roman domination of the whole western Mediterranean; in the second and first centuries B.C.E., successive victories in Greece, Anatolia (Turkey), Syria, and Egypt extended Rome’s power and wealth eastward.

The rule of the first Roman emperor, Augustus (27 B.C.E.–14 C.E.), marks the beginning of a four-hundred-year period, unique in history, during which a single political power governed the whole Mediterranean. Travel and trade were relatively free throughout the region and there was intensive cultural interaction. Travel was slow, however: it was a five-month voyage from the Pillars of Hercules (Straits of Gibraltar) to Antioch at the eastern end of the Mediterranean. Only foods that were dried, pickled, or salted, and only special wines (see below), would withstand the rigors of such a journey.

Crises in the third and fourth centuries C.E. led to the division of the empire into two parts, which had quite different fates. The Eastern Roman Empire was directly continued in the Byzantine Empire. The Western Roman Empire collapsed, finally disappearing in 476 C.E. However, the “barbarian” kingdoms that took its place inherited Roman dietary ideas and developed a way of life that had many Roman features.

Even before those eastern conquests, Romans had become rich enough to spend their wealth enthusiastically on imported luxuries. Lavish banquets became fashionable, and the price of slave cooks rose steeply. Moralists inveighed against these developments, but they did so in vain. Meanwhile, other changes had affected the Roman diet. The acquisition of new territories provided the opportunity for experimentation in agriculture and food production. Romanization in the provinces encouraged people to demand that what was available in the capital should also be available more widely, especially to Roman legionaries and provincial administrators. The province of Britain, whose conquest began in 43 C.E., provides an example: vines, peaches, walnuts, celery, coriander (cilantro), carrots, and several other important foods were first transplanted to that province in Roman times. Wine, olive oil, olives, figs, lentils, chickpeas, and rice were among the commodities that Roman traders first exported to Britain in response to the popularity of Roman fashions in that region.

Many special features of Roman administrative and economic life left their marks on the food and cuisine of the vast region that was once the Roman Empire. Great frontier armies, whose zones of recruitment ensured movement and mixture of populations, required the delivery of reliable, standardized supplies on well-built roads. Inscriptions show that periodic markets existed: they were held every eight days in Italian towns, twice a month in North Africa, and three times a month in Asia Minor.

### The Literature of Food

The oldest Latin prose text, written about 175 B.C.E., is *De Agri Cultura* (On farming) by the statesman Cato. This work focuses on the two great cash crops of Italy—wine and olive oil—and also includes recipes for cakes and flavored and medicinal wines suitable for farmhouse production. The tradition of Roman agricultural texts culminated in Columella’s detailed manual *On Agriculture*, written about 50 C.E. Columella provides much information on food throughout the manual, as well as a long section (Book 12) full of recipes for household preserves and other food products. Written at about the same date, the Latin encyclopaedia *Historia Naturalis* (Natural history) by Pliny the Elder contains eight books (12–19) on plants and their uses, with special attention to fruits and vegetables. Book 14 is devoted entirely to grapes and wine. Although Latin was the native language of Rome, many medical and scientific texts of the Roman

Empire were written in Greek: examples are a dietary manual, *On the Properties of Foods*, by the imperial physician Galen (129–199 C.E.), and a medical and dietary textbook by one of his successors, Oribasius (c. 325–400 C.E.). These dietary manuals list foods in great detail, which allowed the reader to work out suitable diets. The manuals also make allowances for seasonal factors and each individual’s constitution, lifestyle, and current state of health, in accordance with ancient medical theories. (For English translations of all the texts named in this paragraph see the bibliography.)

Poetry and literary prose give a different perspective on food from that of the technical texts. The personal poetry from the period of Augustus is full of insights on food and dining among the elite, demonstrating the growth of gastronomy and the ways in which food articulated social relations. Authors of this period include Propertius, Horace, and Ovid. Written about one hundred years after the time of Augustus, the picaresque novel *Satyricon* by Petronius mocks the luxurious lifestyle of the new rich. The series of biographies of emperors by the imperial archivist Suetonius (*Lives of the Twelve Caesars*, written about 115 C.E.) provides a glimpse into palace lifestyles, in which feasts sometimes turned into Roman orgies. Lives of poorer people are depicted in the fictional *Metamorphoses* (often translated under the title *The Golden Ass*) by Apuleius (born 125 C.E.), and later in the biographies of Christian hermits and saints.

It was common in Roman writing to despise complicated dishes designed for show rather than for taste. Yet, in practice, Romans reveled in the spices and deli-

Interior of the bakery of Sotericus at Pompeii, Italy. © MIMMO JODICE/CORBIS.

cacies of the whole ancient world: the pepper of south India and even the cloves of the Spice Islands were prized luxuries. In the recipes of Apicius, the flavor of the main ingredient is often enhanced with ten or fifteen spices and herbs. Rich households must have spent much money and slave labor on the finding of rare ingredients and the elaboration of showpiece dishes. The parrot wrasse (a type of fish) and the dormouse fetched high prices not because of their flavor but because of the way they looked on the table. Peacocks, and peahens' eggs, were in demand among gourmets for their rarity more than their quality.

It was also a commonplace to boast of the freshness and simplicity of the farm produce that one was offering to one's guests. There is a tradition of poetic "invitations to dinner" that demonstrate changes in style as well as individual responses to food fashion, extending from about 50 B.C.E. to 110 C.E.: authors of this genre include Catullus (*Poems* 13), Horace (*Epistles* 1.5; *Odes* 3.29, 4.12), Martial (*Epigrams* 5.78, 10.48, 11.52), Juvenal (*Satires* 11), and Pliny the Younger (*Letters* 1.15).

### Staple Foods and Major Flavorings

Rome's status as an overgrown city-state was signaled in one of the special privileges enjoyed by inhabitants of the city: the free bread ration. Interruptions in the wheat supply led to riots. Rome's annexation of Egypt, after Cleopatra's suicide in 30 B.C.E., ensured the continuity of the supply. Thereafter, huge grain ships left Alexandria regularly throughout the sailing season, bringing wheat to Ostia at the mouth of the Tiber. It was on such a ship that St. Paul reached Italy after having been shipwrecked on Malta. Roman bakers baked leavened bread, both white and wholemeal. Small-scale baking required a dome-shaped baking-crock (*testum* and *clibanus*). Archaeologists often find fragments of these. A commercial bakery, complete with fossilized loaves, has been excavated at Pompeii.

The traditional staple food of early Italy had been not wheat bread but *puls* (porridge made from emmer wheat). The staple diet of the Roman provinces varied considerably, depending on climate and local custom. Barley, although widely considered a respectable, even desirable, staple food in ancient Greece and Italy, was viewed by Roman soldiers as punishment rations. This increased the demand for wheat wherever Roman armies were stationed.

Always in use in the Roman kitchen were olive oil, fish sauce, and wine. All three were manufactured and distributed on a large scale. *Garum* was the major source of dietary salt: scarcely any *Apicius* recipes call for pure salt. Grape syrup was also much used in flavoring, as were honey and dates. Many recipes begin with the instruction, "Pound pepper and lovage," a reminder that both exotic spices and local herbs were appreciated (lovage, native to Liguria in northern Italy, is a bitter culinary herb resembling parsley). Other commonly used flavor-

ings were onion, mustard, dill, fennel, rue, savory, thyme, mint, pine kernels, caraway, cumin, ginger, and *asafoetida*, the central Asian substitute for the *silphium* that the Greeks had appreciated so much.

Pliny the Elder and Galen—both of whom were wine enthusiasts, judging from their writings—provide full information on the wines that Romans drank with their meals. Italy had many fine wines to boast of. The famous Caecuban vineyards in Latium (modern Lazio) succumbed to urbanization, but Falernian wine, from hillsides in northern Campania, maintained its reputation throughout the empire. In the world's oldest recorded tradition of wine vintage years, fine wines were labelled with the name of one of the consuls elected for the year. The Opimian vintage (121 B.C.E.) was legendary: Opimian wines were served, already 160 years old, at a banquet given for the emperor Caligula in 39 C.E. Horace addressed an amusing poem to a jar of wine: "born, as I was, when Manlius was consul," (that year was 65 B.C.E.). It was in Roman times that the wine-growing regions of Spain and southern Gaul (France) first came to real economic importance. Long-distance transport of wines was less risky if they were "cooked" and sweetened with honey or grape syrup; it was in this form that Greek wines were enjoyed in Rome. Roman territory eventually extended northward far beyond the latitude at which grapes ripen to full sweetness. In these regions, including northern Gaul and Britain, Roman legionaries developed a taste for local beer, which was usually brewed from malted barley.

### Food in Roman Society

City dwellers in imperial Rome, many of whom lived in apartment blocks, had little opportunity to cook: cooking required an open fire, often an unacceptable risk. However, street food was always available to the city dweller. Street stalls and cookshops sold cakes and sweets, mulled wine, hot sausages, hot chickpea soup, and porridge. "In the tavern all are equally free," wrote Juvenal (born 67 C.E.) with an undertone of disapproval. He continues, "all drink from a common cup, the couch is barred to no man, the table is no closer to one than it is to another," (*Satires* 8.177-8). The philosopher Seneca the Younger (died 65 C.E.) gives us the sounds of the busy street just outside his apartment window: "pancake-sellers and a sausage-vendor and a confectioner and all the proprietors of cookshops selling their wares, each in his distinctive accent" (*Letters to Lucilius*, 56).

Poor countryfolk had to depend largely on food from their own fields and gardens, supplemented by herbs and fruits gathered from the wild. Meat and fish were uncommon in their diets. For a sense of the flavors of a Roman peasant diet, see the poem "Moretum" (c. first century B.C.E.).

For the peasant population of the ancient countryside, food preparation was a shared task, but in general it was the special responsibility of women. Large house-

holds had kitchens staffed with slaves, the skilled cook himself often being an expensive and carefully-chosen acquisition.

Romans tended to eat little during the first part of the day: a breakfast (*ientaculum*) was a snack that many did not trouble to take at all, and only the greedy wanted a heavy lunch (*prandium*). There was no better preparation for a full evening meal, (*cena*) the one big meal of the day, than a couple of hours at the baths. These were fashionable meeting places, ideal locations for informal business discussions. One could easily spend a whole evening there, for food and wine were available at bars and restaurants.

Typical larger Roman houses had a special dining room, the *triclinium*. Three couches arranged in a U-shape, each large enough for three diners, surrounded a central table. A house with a big enough garden might have had a garden dining area, as well, which was shaded by vines and creepers, with three stone couches sloping gently upwards to the middle (cushions and pillows made these comfortable). The open side of the square was for waiters to come and go.

Servants took off guests' sandals as they reclined and brought water to wash their hands. A sequence of dishes began with the appetizer or hors d'oeuvre (*gustus*), followed by an aperitif such as honeyed wine (*mulsum*) or spiced wine (*conditum*). The appetizers were generally more varied and more costly than the main course, though not as bulky. At one religious dinner attended by Julius Caesar, sixteen hors d'oeuvres awaited the priestly celebrants. The appetizers ranged from sea urchin and clams to slices of venison and wild boar.

The main courses were accompanied by bread and wine. Diners ate with their hands, with the occasional help of a knife. Waiters were constantly coming and going, bringing new courses, clearing away dishes, and supplying perfumed water for finger-rinsing. Music and dance from hired performers, usually slaves, often accompanied the drinking, which tended to continue long after the meal itself was over. The emperor Augustus preferred to entertain his guests by employing traditional storytellers.

A napkin, which lay in front of the diners as they reclined, might serve as a knapsack to take home the little gifts (*apophoreta*) with which a host would regale his friends as they departed. Similar gifts were given to dependents not lucky enough to be invited to a real dinner. Martial (c. 100 C.E.) wrote a collection of short poems intended to accompany such gifts. They are the most obvious sign that hospitality helped to articulate the patron/client relations that permeated Roman society. The Greek satirist Lucian (second century C.E.) wrote a convincing sketch of daily life in a rich Roman household and addressed it to a friend who had been offered a post as private tutor. Placed at the lowest table, Lucian warned, the friend would be sneered at by slaves and

would taste little of the fine cuisine except the mallow leaves that garnished the serving dishes (*On Salaried Posts in Great Houses*, 26).

Among upper-class Romans, unlike Greeks, the sexes were not segregated at meals. It was said that Roman women once sat demurely at the feet of their husbands' dining couches, but by imperial times the women also reclined. It was said, too, that in the old days women did not drink wine, and that the kiss a Roman husband gave his wife when returning home was a way of assuring himself that this rule had been kept.

#### BIBLIOGRAPHY

The standard modern survey of Roman food and the most detailed study of Roman wine are both in French: André, Jacques. *L'alimentation et la cuisine à Rome* [Food and cuisine in Rome]. 2d ed. (Paris: Les Belles Lettres, 1981. Tchernia, André. *Le Vin de l'Italie romaine* [The wine of Roman Italy]. (Rome: Ecole Française de Rome, 1986). Plenty of useful information in English will be found in: Alcock, Joan P. *Food in Roman Britain*. (Brimscombe Port, Gloucestershire, U.K.: Tempus, 2001); Fleming, Stuart J. *Vinum: the Story of Roman Wine*. (Glen Mills, Pa.: Art Flair, 2001); Garnsey, Peter. *Food and Society in Classical Antiquity*. (Cambridge: Cambridge University Press, 1999); Slater, William J., ed. *Dining in a Classical Context*. (Ann Arbor: University of Michigan Press, 1991); White, K. D. *Roman Farming*. (London and New York: Thames and Hudson, 1970); Wilkins, John, David Harvey, and Mike Dobson, eds. *Food in Antiquity*. (Exeter, U.K.: Exeter University Press, 1995).

Modern translations of most of the Roman literary texts cited in this article are easily found in libraries. For examples of Christian biographies see Russell, Norman, trans. *The Lives of the Desert Fathers*. (Oxford: Mowbray; Kalamazoo, Mich.: Cistercian Publications, 1981). The following is a list of specialized Roman sources on food that are available in English: Dalby, Andrew, trans. Cato, *On farming*. (Totnes, Devon, U.K.: Prospect Books, 1998); Ash, Harrison Boyd, E. S. Forster, and Edward H. Heffner, trans. Columella, *On Agriculture*. 3 vols. (Cambridge, Mass.: Harvard University Press, 1941–1955); Rackham, H., et al., trans. Pliny, *Natural History*. 10 vols. (Cambridge, Mass.: Harvard University Press, 1938–1963); Grant, Mark. *Galen on Food and Diet*. (London and New York: Routledge, 2000); Grant, Mark. *DiETING for an Emperor: A Translation of Books 1 and 4 of Oribasius' Medical Compilations*. (Leiden: Brill, 1997).

For Roman recipes with modern adaptations see: Grant, Mark. *Roman Cookery: Ancient Recipes for Modern Kitchens*. (London: Serif, 1999); Dalby, Andrew, and Sally Grainger. *The Classical Cookbook*. (Los Angeles: J. Paul Getty Museum; London: British Museum Press, 1996. See also under Apicius).

For information on the spice trade see: Miller, J. Innes. *The Spice Trade of the Roman Empire*. (Oxford: Clarendon Press, 1969); Dalby, Andrew. *Dangerous Tastes: the Story of Spices*. (London: British Museum Press; Berkeley: University of California Press, 2000). For works on country people and their food see: Frayn, Joan M. *Subsistence Farming in Roman Italy*. (London: Centaur Press, 1979); Kenny, E. J., ed. *Moretum: the Ploughman's Lunch*,

*A Poem Ascribed to Virgil* (Bristol: Bristol Classical Press, 1986). For information on markets see: Frayn, Joan M. *Markets and Fairs in Roman Italy*. (Oxford: Clarendon Press, 1993); de Ligt, L. *Fairs and Markets in the Roman Empire*. (Amsterdam: Gieben, 1993).

Emily Gowers, in *The Loaded Table* (Oxford: Oxford University Press, 1993) explores the hidden meanings of food in Latin poetry: she makes a special study of the poetic invitations to dinner. Andrew Dalby's *Empire of Pleasures: Luxury and Indulgence in the Roman Empire* (London and New York: Routledge, 2000) is a survey of the empire's foods and other luxuries, showing their use in constructing Roman imperial identity. The best outline of Roman daily life, dated in some ways, but well documented and not superseded, is: Carcopino, Jérôme. *Daily Life in Ancient Rome*. (New Haven: Yale University Press, 1940; London: Routledge, 1941).

Andrew Dalby

**RUSSIA.** Russian food is typically hearty in taste, with mustard, horseradish, and dill among the predominant flavorings. The cuisine is distinguished by the many fermented and preserved foods that are necessitated by the short growing season of the Russian North. Cabbage (sauerkraut) and cucumbers (pickles) are enjoyed greatly, as are a wide range of salted fish, vegetables, and meats. Fish and produce are also frequently dried or brined for lengthy storage. Foraged foods, especially mushrooms, are important to both Russian diet and culture. Although the Russians have never excelled at making hard cheeses, they prepare an expert array of fresh dairy products, such as creamy curd cheese (*tvorog*) and various cultured yogurt-like preparations (*riazhenka*, *prostokvasha*), in addition to excellent sour cream (*smetana*). Honey is the traditional Russian sweetener and is used as the basis for drinks, fruit preserves, and desserts. Early condiments (known as *vzvar*, from the word "to boil") consisted of onions or beets cooked slowly in honey until rich and sweet.

Russian cuisine is known for its extensive repertoire of soups. The national soup (*shchi*) is made from cabbage, either salted (sauerkraut) or fresh, in which case it is known as "lazy" *shchi*. The beet soup (*borsch*) commonly associated with Russian cuisine is actually native to Ukraine, to the south of Russia; it became popular abroad following Jewish emigration from that region. Soup is traditionally served at the midday meal and is accompanied by an assortment of small pies, croutons, or dumplings. The Russian diet tends to be high in carbohydrates, with a vast array of breads, notably dark sour rye, and grains, especially buckwheat (*grechnevaya kasha*).

The national cuisine is further distinguished by wonderful pies filled with myriad combinations of meat, fish, or vegetables. Prepared in all shapes and sizes, pies are both festive and a practical way to use up leftovers. The most elegant pie is, perhaps, the *kulebyaka*, a multilayered fish pie with thin pancakes (*blinichi*), kasha, and salmon

(including the spinal marrow or *viziga*) that was adopted into French cuisine as *coulibiac*.

### Diet of the Early Slavs

Early Slavic agriculture was largely grain based. Hearty crops like rye, oats, barley, buckwheat, spelt, and millet provided the mainstay of the diet, most often in the form of gruel or baked into cakes made of meal sweetened with honey and flavored with berry juice. Although wheat was cultivated in the South, it remained of secondary importance. From the Scythians, a Eurasian tribe that roamed the steppes of southern Russian from the eighth to the fourth centuries B.C.E., the early Slavs learned how to make leavened breads, using primarily sourdough. Grains were supplemented by legumes (*gorokh*), an important source of protein. Freshwater fish and wildfowl, both of which were abundant, provided additional sources of protein. Vegetable and nut oils (especially hempseed and linseed), foraged mushrooms and berries, and orchard fruits such as cherries, pears, plums, and apples supplemented the largely carbohydrate diet. Also critical were cultivated vegetables, including turnips, beets, radishes, onions, garlic, cabbage, and cucumbers. Turnips were an important staple until the widespread (and enforced) cultivation of the potato in the nineteenth century. Given the geographical limitations on agriculture, much of the population lived in a state between hunger and starvation, and up through the twentieth century Russia experienced frequent famines.

The earliest domestic livestock included cows, pigs, sheep, and goats; chicken, ducks, geese; turkey was introduced somewhat later. Butter was traditionally prepared from cow's milk by heating sour cream, rather than by churning it from sweet cream, a method the Russians learned only in the eighteenth century from the Finns.

By the twelfth century the Russians were already boiling down salt from water from the White Sea, but salt remained an expensive commodity that only the wealthy could afford. Even those who could afford salt used it sparingly. A seventeenth-century German visitor Adam Olearius, complained that "in Moscow, they use coarse salt fish, which sometimes stinks because they are thrifty with the salt. Nevertheless, they like to eat it." In general, the affluent had a plentiful assortment of fish, meat, fruits, vegetables, and grains, a diet that contrasted greatly with the meager rations of most of the population, who subsisted on little more than oatmeal gruel (*tolokno*) and rye bread. Although the soil around Moscow and in the south of Russia yielded excellent produce, the growing season was short, and most people did not have access to a variety of foods.

### Cooking Methods

Apart from the methods used for preserving food, boiling and baking were the most common ways of preparing foods (frying and grilling were also practiced). By 1600 rich and poor alike were cooking food in the Russ-

ian masonry stove (*pech'*), which was massive enough to take up nearly one-quarter of a peasant cottage. This stove defined the living space, demarcating the female and male spheres of the room into the cooking area (female) to the left of the hearth, and the icon-dominated “beautiful corner” (male) to the right. The earliest stoves had no flue, causing smoke to issue directly into the cottage; more prosperous families replaced these “black” stoves with more refined “white” stoves fitted with chimney pipes. Russian peasants generally believed that the stove held mystical powers, with a house spirit (*domovoi*) residing beneath or behind it.

Food could be prepared in many different ways on the stove—boiled, baked, steamed, roasted, and braised. Many of Russia’s most typical dishes reflected the specific properties of the stove, which blazed and was very hot after firing and then gradually diminished in the intensity of its heat. Breads and pies were baked when the oven was still very hot, either right in the fire’s ashes or immediately after they had been scraped out. Once the temperature began to fall, grain dishes could cook in the diminishing heat, which ensured that porridges were crusty on top and creamy within. As the oven’s heat continued to subside, the stove was ideal for the braised vegetables and slow-cooked stews that represent the best of Russian cooking. Dairy products were cultured in any residual oven heat.

Whether the medieval Russian diet was varied or sparse, the cooking methods for rich and poor were nearly

analogous. Although Tsar Peter the Great introduced the cooktop (*plita*) from Holland in the eighteenth century, and metal stoves became common in urban dwellings in the nineteenth century, the Russian stove remained in use in the countryside well into the twentieth century.

### Influence of the Russian Orthodox Church

In 988 Grand Prince Vladimir of Kievan Russia adopted Christianity for his people. Many of the existing pagan celebrations, such as those marking the seasonal solstices, were transformed into religious holidays like Christmas and Easter. The Orthodox Church had a profound influence on the Russian diet, dividing the year into feast days (*skoromnyi*) and fast days (*postnyi*). The latter accounted for approximately 180 days of the year. The fast periods largely coincided with times in the agricultural year when food supplies were running low. Most Russians took fasting seriously, strictly following the prescriptions against meat and dairy products. In addition to meatless Wednesdays and Fridays, the Russians also observed extended fasts, the most important of which were the Great Lenten Fast (forty days, plus one week, Passion Week, which precedes Easter), the Christmas or Filippov Fast (the six weeks preceding Christmas), the Fast of Saints Peter and Paul (beginning in late May or June and lasting from one to six weeks, depending on when Easter fell); and the Fast of the Dormition (two weeks in August). On the most stringent fast days (Lent and the Dormition Fast), even fish and vegetable oil were forbidden. Generally, the poorer the household, the more

devoutly it fasted, since meat and dairy products were at best scarce even on non-fast days. For the wealthy, fasting did not necessarily mean deprivation. A mid-seventeenth-century state dinner given on a fast day for the English ambassador Carlisle offered no fewer than five hundred dishes, not one of which was made with meat products. Throughout the nineteenth century, cookbooks offered suggestions for both feast day and fast day meals. In addition to recipes for fish and vegetarian dishes, the cookbooks provided information on substituting nut oils and almond milk for dairy products in cooking and baking.

### Holidays and Ritual Foods

Numerous feast days compensated for the stringent fasts. Feasts were held in celebration of weddings, funerals, and the name days of saints, which the Russians observed instead of birthdays. Many religious holidays were also considered feast days. Just before the rigorous Lenten fast came Butter Week (*Maslenitsa*), similar to Mardi Gras, except that it lasted a full week. Although no meat was allowed, the Russians consumed excessive amounts of dairy products, most often in the form of blinies. These traditional yeast-raised pancakes, made with buckwheat or wheat flour, are porous enough to soak up plenty of melted butter. Topped with caviar, smoked fish, pickled herring, or sometimes jam, the bliny can be traced back to pagan times, when the early Slavs baked round pancakes in the image of the sun to welcome its return at winter's end.

Easter is the most important holiday in the Russian Orthodox year. Throughout Easter week a table is kept laden with food. The two most traditional foods are *kulich*, a tall loaf of bread enriched with eggs, butter, sugar, and candied fruits, glazed with confectioners' sugar, and often topped with a rose; and *paskha*, fresh farmer's cheese mixed with cream and butter and molded into a pyramid shape. Raisins or nuts are used to decorate it with the letters XB for "Christ is Risen."

Virtually every festive occasion calls for a special bread. Pies, such as an elaborate chicken pie layered with vegetables (*kurnik*), are served at weddings; a sweet, pretzel-shaped loaf (*krendel'*) is traditional for name days; and animal-shaped buns are distributed to Christmas revelers. These buns, as well as the lark-shaped breads baked to celebrate the return of the birds in spring, predate the Christian era. Other breads, such as one baked in the shape of a ladder for the holiday of the Ascension, have Christian roots. *Kut'ia*, which is a dish of wheat berries sweetened with honey and flavored with dried fruits or nuts, is traditionally served at funeral repasts.

### The Tradition of Hospitality

The Russian word for hospitality (*kblebosol'stvo*) derives from the words for bread (*kbleb*) and salt (*sol'*). Taken together, they mean a regalement with that which is most basic to life, and that which is a luxury. A large, round

loaf milled from the finest flour (*karavai*) was traditionally presented as a symbol of hospitality or was offered to newlyweds as a housewarming gift. The loaf often had an indentation in the top crust to hold a small dish of salt. The act of honoring guests lies at the heart of the Russian national identity. As counseled by the *Domostroi*, a sixteenth-century manual that teaches household management and piety, guests are sacred; by receiving them well, you also serve God. One should offer guests the very best food available. The Russians took this advice to heart: even the poorest households did not turn strangers away.

The sharing of bread was ritualized in the practice of "begging for crusts," which occurred whenever food shortages threatened the peasantry. Unlike simple begging, which was looked down upon, "begging for crusts" was accepted as part of the natural order: each peasant family knew that the situation could be reversed, and next time they might be the ones in need of food after a bad harvest.

In medieval Russia hospitality to foreigners was expressed through the institution of the *podacha*, a ritualized presentation of food. Privileged guests at the tsar's palace were given confectionery items to bring home at the end of each feast; the amount given was determined by the person's rank. Anyone unable to attend the festivities might have the *podacha* delivered to his residence by couriers, who would parade through the streets of Moscow in a display of the tsar's power and largesse.

Today, the hissing *samovar* or tea urn is the acknowledged symbol of Russian hospitality, ready to serve unexpected guests at a moment's notice. However, this tradition is relatively recent, as use of the samovar became widespread only in the second half of the nineteenth century.

### Alcohol Consumption

The *Primary Chronicle*, Russia's earliest historical record, relates that Grand Prince Vladimir proclaimed "Drinking is the joy of Rus'" when he chose Christianity over Islam, which forbids the consumption of alcohol. From the earliest times the Russians enjoyed alcoholic beverages, especially mead, a fermented honey wine flavored with berries and herbs; *kvas*, a mildly alcoholic beverage made from fermented bread or grain; *berezovitsa*, lightly fermented birch juice; and beer. Distilled spirits, in the form of vodka, appeared only in the fifteenth century, introduced from Poland and the Baltic region. Vodka was originally used for medicinal purposes, but it gradually displaced the older beverages in popularity, and by the seventeenth century spirits were already causing social problems. Because the high taxes on vodka filled the state coffers, the government was not eager to curtail use of the substance (a few privileged noblemen were given the right to produce vodka, but the government basically had a monopoly on its production). In the late nineteenth century the famous chemist Dmitri Mendeleev set the

optimal alcoholic content of vodka at 40 percent spirits diluted with distilled water. Commercial producers capitalized on Mendeleev's pronouncement, and Russia has been known ever since for its excellent vodka.

Tsar Ivan the Terrible established the first taverns (*kabaki*) in the sixteenth century by for the sole benefit of his elite guards. Since then the government has vacillated between strict and lax approaches to vodka consumption, at times encouraging it to build up the state treasury and ease public unrest, at other times curtailing access to the drink. Tsar Peter the Great was known to ply his guests with drink in order to find out what was really going on at court, and he himself engaged in drinking binges that lasted for days at a time. More recently, in the Soviet era, two Communist leaders, Yuri Andropov and Mikhail Gorbachev, attempted to control access to vodka. Their ill-fated attempts caused widespread discontent, as well as severe shortages of sugar, which people purchased in bulk to produce moonshine.

### Eastern Influence on Russian Cuisine

In 945 Russia, though still not unified, initiated trade with Constantinople, the seat of the Byzantine Empire. In exchange for honey and furs, the Russians received rice, spices, and wines. In 1237 the Mongols invaded the Russian principalities, and for nearly two hundred years Russia had to pay tribute to the Golden Horde. The occupation was not without culinary benefits. The Mongols reopened the ancient trade routes between China and the West, which had become too dangerous due to frequent tribal wars. Foods introduced along these routes included noodles and cultured milk products such as *koumiss*, the fermented mare's milk drunk by Turkic nomads.

With Russia's conquest of the Volga region in the mid-sixteenth century, the Russians were able to trade for spices like pepper, saffron, cinnamon, and ginger, as well as rhubarb, which became an extremely lucrative export crop. Also from the Volga region came sweet watermelons from Astrakhan, at the mouth of the Volga, and increased access to sturgeon, sterlet, and caviar from the Caspian Sea.

Tsar Ivan IV (the Terrible; 1530–1584) led a series of Eastern campaigns to subjugate the khanates of Kazan, Astrakhan, and Tatar Bashkiria; in 1582 he also annexed Siberia. This eastward expansion introduced the Russians to *pel'meni*, wonton-like pockets of boiled dough filled with ground meat and onions. The Russians serve these dumplings either with vinegar and mustard or with butter and sour cream. *Pel'meni* are frequently made in large quantities at the beginning of winter and kept frozen outdoors in a bag, ready for boiling into a quick meal. Exotic fresh and dried fruits were also introduced from the East, and raisins and dried apricots have held a prominent place in Russian cuisine ever since.

Tea also arrived in Russia by way of Siberia. As early as 1567 emissaries from Ivan IV had spoken of this strange brew, but it wasn't until 1638 that tea found its way to the royal court. The signing of the Treaty of Nerchinsk in 1689 established regular trade between Russia and China. From then on tea became a valuable commodity, although until the nineteenth century tea drinking was largely confined to Moscow's urban population.

With the expansion of the Russian Empire into the Caucasus and central Asia, beginning in the late eighteenth century and continuing under Soviet rule, dishes from Eastern cuisines entered into the Russian repertoire. From Georgia came grilled meats (*shashlyki*), flattened chicken cooked under a brick (*tabaka*), and herbed kidney beans (*lobio*); from Armenia came flat bread (*lavash*); from Azerbaijan, ground lamb kebabs (*hyulya-kebab*); from Tatar Crimea, fried meat pies (*chebureki*); from Uzbekistan, rice pilaf (*plov*) and dumplings (*manty*); and from Kyrgyzstan, lamb and noodle stew (*lagman*).

### The Era of Muscovy

During the era of Muscovy (from the fourteenth to early eighteenth centuries) the disparity between rich and poor became firmly established, resulting in two very different cuisines. The poor ate little more than bread, gruel, and soup made from vegetables and grains. The wealthy, on the other hand, ate so lavishly that foreign visitors like the French envoy Foy de la Neuville, on a 1689 visit, declared them gluttons. Foreigners generally considered the Russians uncivilized, not only due to their prodigious appetites, but also due to the pleasure they so openly expressed from their meals via belching and other bodily sounds.

The wealthy indulged in feasts that lasted for hours. Pickled or salted beef, ham, suckling pig, elk, boar, lamb, and rabbit all appeared on the table. Swan was considered the most luxurious of birds, although the wealthy also enjoyed crane, heron, black grouse, hazel hen, partridge, lark, goose, duck, and chicken. Veal was rarely consumed, and the Russian Orthodox Church forbade eating doves, since the birds symbolized the Holy Spirit. Hot and cold soups, noodle dishes, roasts, and sauces were seasoned with onion, garlic, pepper, saffron, and sometimes savory. The combination of sweet and sour so typical of medieval foods throughout Europe was especially compatible with Russian tastes. Rich, dark swan meat was often served with vinegar or a combination of sour milk, pickles, and prunes.

The tsar's table was furnished year-round with fish from distant waters, transported whole or in pieces, fresh or salted, or brined in barrels. Sturgeon and sterlet were brought live in tanks from the Caspian Sea to Moscow; whitefish came from Lake Ladoga; and several varieties of salmon were sent overland from the Kolsk Peninsula in the far North. Pike, bream, perch, pike-perch, and many other sorts of excellent fish were caught in the rivers and ponds around Moscow.

## CAVIAR

The Russians were the first to develop a caviar industry based on the several varieties of sturgeon that they fished, and the world's best caviar still comes from the Caspian Sea. The thirteenth-century court of Grand Prince Yaroslav of Novgorod had a special sturgeon master to oversee the procurement, preparation, and serving of sturgeon. The roe was particularly relished. (Although Russians consider sturgeon roe the finest, they also enjoy the eggs from such fish as burbot, white salmon, pike, carp, and grayling, although technically this roe is not considered caviar.)

Making caviar is extremely labor-intensive, as the fish eggs are both fragile and perishable. The roe must be extracted by hand, then kept cold during processing (generally at 28°–32°F [–2°–0°C]) to keep it fresh. Salt is added to lower the temperature at which the eggs will freeze, as well as to help preserve them. The best fresh caviar, which contains roughly 4 percent salt, is known as *malosol* ("little salt" in Russian). Today, for exports to Europe, the Russians also add a small amount of borax to the roe, which works as a preservative and reduces the need for salt. Borax gives the eggs a slightly sweeter taste and makes them a bit oilier. Russia omits the borax for caviar imported into the United States, which prohibits the sale of borax-treated eggs.

The flavor and quality of caviar depend on the type of sturgeon it is taken from. The most common types, in decreasing order of size, are beluga, osetra, and sevruga. Beluga sturgeon can weigh over two thousand pounds; its roe is a pearly gray and has a very subtle flavor. Many Russians prefer the strong flavor of *payusnaya* or pressed caviar, made from eggs that have been broken in processing or from very mature eggs pressed into a concentrate the consistency of thick jam.

Caviar was standard fare for the wealthy on the numerous fast days dictated by the Russian Orthodox

Church, when meat and dairy products were proscribed. Medieval Russians often left the roe in the egg sac. They seasoned it with salt and pepper, then dusted it with flour and fried it, serving an onion, cranberry, or saffron sauce on the side. Sometimes they offered the cooked caviar cold, cut into slices and flavored with an herb vinegar or mustard sauce. For the Muscovite dish *kal'ia*, pressed caviar was cut into thin rounds, then placed in an earthenware pot with chopped onion, pepper, pickles, pickle brine, and water. This mixture was steamed in the Russian stove, with additional pepper added upon serving. Nineteenth-century culinary fashion called for slicing pressed caviar and serving it in a napkin as "serviette caviar." Elena Molokhovets, Russia's Mrs. Beeton, suggested a more practical use for pressed caviar. In her classic cookbook, *A Gift to Young Housewives*, she explains how to clarify bouillon with pressed caviar, using one-quarter pound of the caviar in place of two egg whites.

By the mid-nineteenth century the finest sturgeon caviar had become rare enough that it was generally served unadorned. Astrakhan caviar, with its large, gray grains, was considered the ultimate roe. It was served on toast points or mounded in a pyramid and decorated with lemon wedges with croutons on the side. Late-nineteenth-century cookbooks sometimes cautioned against buying caviar with a greenish tinge, which was caused by treatment with a dye containing copper salts.

All varieties of sturgeon are endangered, due to environmental pollution and poaching (there is a thriving black market in caviar in southern Russia). The political and economic chaos that afflicted Russia after the collapse of the Soviet Union caused many foreign purveyors to turn to Iran for the highest quality caviar. Now, in order to keep up with world demand for the roe, scientists are experimenting with farm-raised sturgeon, particularly in the Caspian waters belonging to Kazakhstan.

### **Eighteenth-Century Reforms**

The reforms carried out by Peter I (the Great; 1672–1725) affected virtually every aspect of Russian life. Upper-class women, who had previously lived in seclusion, were allowed into male company and could eat at the same table as men. Peter introduced napkins from Holland (until his reign, tables had been covered with short cloths, the edges of which were used to wipe the hands and mouth while eating). Since large joints of meat were carved and served in small pieces at table, several people would generally share forks and knives among them, but Peter encouraged the use of individual two-pronged forks.

In the kitchen, the most significant development for Russian cuisine was the introduction of the Dutch range, which, contrary to the traditional Russian stove, relied on a cooktop more than on oven chambers. This change necessitated more labor-intensive cooking methods as well as new utensils. Saucepans, for instance, replaced the customary earthenware pots.

Peter was eager to acquaint Russians with new food-stuffs and culinary methods that he had learned on his extensive travels. From Holland he imported not only hothouse vegetables and fruits (pineapples became a particular Russian passion), but also aged cheeses, which the

Russians did not know how to make. He sought grape varietals that could thrive in southern Russia and placed the two-centuries-old Astrakhan winery under the supervision of a French vintner to increase its quality and production.

In 1712 the imperial court moved from Moscow to Saint Petersburg. The design of the commercial center (*Gostinyi dvor*) incorporated a canal right in the building so that boats could unload their wares on site. Petersburg's significant foreign population influenced the city's eating habits, and foods such as waffles and artichokes found welcome reception. Furthermore, the young Russian men whom Peter had sent abroad to further their education returned with new tastes. Seeking more variety in their diet, they began to import exotic foods. When Peter hired a Saxon as his private chef, the nobility soon followed suit. Thus Russia's first foreign chefs came primarily from Saxony, Bavaria, and Austria.

Because the founding of Saint Petersburg had caused trade to decline at the far northern port of Archangel on the White Sea, in 1721 Peter issued an *ukaze* ordering his people to eat ocean fish. Previously the Russians had used only freshwater fish from rivers and lakes, and many were suspicious of such strange species as cod, whiting, and mackerel.

### French Influence on Russian Cuisine

The culinary changes wrought during Peter's thirty-six-year reign were so great that by the time his daughter Elizabeth seized the throne in 1741, lemons and oranges were no longer a luxury, and English beer was in greater vogue than traditional Russian brews. As the century progressed, more and more European influences came to bear on traditional Russian methods. The vocabulary introduced into Russian over the course of the eighteenth century reveals influences from the Dutch, German, English, and ultimately French cuisines. By the close of the eighteenth century, food in the homes of the wealthy was unabashedly French, and Russia's most affluent families employed French chefs, whose style supplanted the German influences of Peter's era.

With so much foreign influence, Russian cuisine lost its simple national character and became increasingly complex. By the end of century, meat was cut into small pieces that demanded complicated handling, as opposed to the large joints of meat that had been roasted or braised in the great Russian stove, or grilled on a spit. As the nineteenth century drew near, many French dining habits were firmly entrenched in Russia, although sometimes with a Russian twist. One practice that came into vogue among the aristocracy was the open table, at which any nobleman, invited or not, was welcome to dine. The conservative prince Mikhail Shcherbatov, in his treatise *On the Corruption of Morals in Russia*, complained that the nobility's excessive socializing at table led to moral deterioration. He was troubled that the nobility gave so little thought to the relationship between the food served and

the religious obligations underlying it. Even so, Peter the Great's reforms and the subsequent refinements to the table broadened and polished Russian cuisine. Adapting western trends to their own needs and tastes, the Russians ultimately made their table quite sophisticated.

### Table Service and Meal Times

The Russian peasantry ate their meager fare from a communal bowl, with each individual wielding his or her own spoon. The wealthy, however, sat down to a vastly different table, which was also distinct from its European counterparts. By the seventeenth century society meals throughout Europe were served in the style known as *service à la française*, which meant that for each course, all of the foods were set out on the table, ranked according to size and symmetrically arranged. The Russians ate in a manner that came to be known as *service à la russe* (it eventually replaced the French style of service in Europe in the late nineteenth century). Here the table was not previously laid with the foods for each course. Instead, each dish was brought individually to the table and presented with fanfare before being removed to the kitchen or sideboard for carving. Each diner received a portioned serving, which ensured that the food was still hot and at the peak of freshness. Furthermore, diners were not limited to the foods located within reach. The drawback of *service à la russe* was that it entailed a large and well-trained staff.

Under Peter the Great, the multicourse banquets typical of the Muscovite era began to evolve into the sequence of four courses that is familiar today. Peter's war with Sweden and his travels in Holland resulted in the introduction of the lavish *zakuska* (hors d'oeuvres) table that has become the hallmark of Russian cuisine. Adapted from the Swedish smorgasbord, an array of salted and smoked foods, including caviar, salmon, sturgeon, herring, pickles, and ham, is offered before the main course. Open-faced sandwiches with meat or cheese reflect a direct borrowing from Dutch practice. After the *zakuski*, soup is served, then a main course, followed by dessert.

Meal times were rather flexible. The wealthy, having no immediate tasks to attend to, often slept late and did not have breakfast until mid-morning. The main meal of the day (*obed*) took place at around 2:00 P.M., followed by a late-afternoon collation or tea, then supper between 8:00 and 10:00 P.M. Peasant families had more structured mealtimes. Breakfast (*zavtrak*) was typically eaten at 5:00 or 6:00 A.M., followed by the so-called second breakfast (*vtoroi zavtrak*) at around 10:00 A.M., providing a break from the day's labors. Dinner was eaten any time between 12:00 and 2:00 P.M., with a midday snack (*poludnik*) at 4:00 or 5:00 P.M. Supper (*uzhin*) was generally served at 8:00 P.M., and, after tea drinking became an established custom in the late nineteenth century, tea (*chai*) often followed. For those who could afford a variety of foods, the Russian breakfast was a hearty affair, complete with porridge (often buckwheat or semolina), smoked or pickled

fish, and eggs or pancakes. The main meal of the day was still not considered complete without a soup course before the entrée.

### Revolutionary Changes

The indulgent lifestyle of the aristocracy and gentry came to an abrupt end with the Revolution of 1917 and the subsequent establishment of the Soviet Union. The new Bolshevik government undertook a radical transformation of social life, promoting as one of their platforms the liberation of women from kitchen drudgery. To this end, vast communal dining facilities (“factory kitchens”) were set up. However, because the food was bad, and most families did not like the impersonal cafeteria style of these facilities, the experiment ultimately failed. What did take hold, however, were communal kitchens in urban houses that had been requisitioned by the government. The great influx of people into the cities following the Revolution of 1917 caused a housing shortage that led to the creation of communal apartments, with sometimes as many as a dozen families sharing a kitchen. Communal kitchens, some of which still exist, contributed to the disintegration of family life and created social tensions.

The political and economic turmoil of the Civil War (1917–1922), coupled with drought in the Volga region, caused a severe famine between 1921 and 1922, in which nearly half a million people died. But this loss of life is small in comparison to the many millions who perished during Joseph Stalin’s enforced collectivization of agriculture, which he carried out between 1929 and 1934, especially in Ukraine. Under this policy, private farms were destroyed and agriculture organized into state-run collective farms (*kolkhozy*). Collectivization proved disastrous for Soviet agriculture, as it was inefficient and discouraged personal initiative. The Soviet Union was forced to import much of its grain from the United States and Canada and frequently suffered from food deficits.

### The Soviet Era

The Soviet Union was never a fully egalitarian society. Most of the populace subsisted on a monotonous diet of poor-quality food, but the government and cultural elite had access to special stores and goods, so they were able to eat well. Although the government ensured that no one went hungry (all factory workers, for instance, received a free lunch at state expense), the average diet was not especially nutritious, as it was low in fresh fruits and vegetables.

The Soviet period was marked by extraordinary hardship. Following collectivization and the political purges of the late 1930s, the Russians endured World War II, also known as the Great Patriotic War. During the Siege of Leningrad (1941–1944), which lasted for nearly nine hundred days, roughly one million people died of starvation. At the most critical point in the siege, the bread ration for factory workers was only 250 grams (8.8 ounces) a day, 125 grams (4.4 ounces) for all others,

with no other food available. Leningraders resorted to eating whatever they could scavenge from the city or find in their apartments, including tooth powder, Vaseline, glycerine, cologne, wallpaper paste scraped from the walls, flour dust collected from cracks in the kitchen floorboards, and spattered grease that was licked from the kitchen walls.

Although life stabilized after the war, the Soviet era was generally characterized by a low standard of living. Shopping was especially difficult, with long lines even for basic foodstuffs. There was very little variety. When so-called deficit items did suddenly appear, shoppers had to stand in line for hours. The vocabulary reflected this reality: products were “obtained” (*dostat*) rather than “bought” (*kupit*). Because of the hierarchy of food distribution, country dwellers flooded daily into Moscow, increasing the crowds and further limiting availability.

The state food stores had very little to offer, but decent foodstuffs could be purchased at the farmers’ markets, where entrepreneurs from Georgia, Armenia, and central Asia sold lemons, melons, and high-quality meat and produce, often at steep prices. To survive, most Soviet citizens became adept at working the unofficial barter economy, and they knew how to take advantage of the black market. Restaurants were few; those that existed frequently offered only one item from their menu and subjected diners to surly service. Therefore most Russians ate at home. The Soviet-era kitchen table became the site of the most important social interactions, where information was exchanged, poetry recited, politics argued, friendships expressed. Despite the food shortages, the difficulty of shopping, and the cramped living space, Russians still took pride in being generous toward their guests, and the tradition of hospitality endured.

### Post-Soviet Russia

The Soviet Union was officially disbanded at the end of 1991. The following year saw the introduction of stringent market reforms, which brought economic hardship to the general population. With a safety net no longer in place, beggars appeared on the streets. The countryside, in particular, suffered from insufficient food. Russia’s economic problems were exacerbated by the crash of 1998, when the ruble lost two-thirds of its value. Still, the Russians are a resourceful people, and in the early twenty-first century the economy was back on its feet.

The collapse of the Soviet state initially brought a rash of investors to Russia, and numerous fast-food chains, such as McDonald’s, gained a foothold. In response to so many Western imports, a feeling of national pride gradually emerged, and domestic chains like *Russkoye Bistro* began to compete with the foreign establishments. Homegrown products again appeared on the market when the economic turmoil of the 1990s caused many foreign firms to leave. Once the economy stabilized, many restaurants opened that offered expensive and elegant pre-Revolutionary fare, nostalgic coun-

try-style cooking, and ethnic cuisine. After seventy years of isolation under Soviet rule, the populace was eager to experiment with new tastes.

With the appearance of self-service grocery stores, shopping was simplified, and it was no longer necessary to stand in line for food. However, one might question whether shrink-wrapped tomatoes imported from the Canary Islands represent progress when locally grown produce can be bought at the market or at curbside kiosks. The slick grocery stores with their aisles of imported goods and the expensive restaurants were status symbols for the wealthy class of New Russians who had money to spare: the majority could not afford them. These New Russians also bought food magazines (unheard of during the Soviet era) and cookbooks: both the French Cordon Bleu cooking course and the *Hare Krishna Book of Vegetarian Cooking* were translated into Russian. Young Russians became increasingly aware of diet and nutrition, the down side being that eating disorders began to appear.

Meanwhile, average Russians could only admire the glossy publications and the wide variety of foods, which were beyond their means. Police in a number of cities have had to put Operation Harvest into effect to protect the potato fields—which were now private property—from hungry poachers. Significantly, the consumerism of the moneyed class was balanced by a return to spiritual values, as many Russians once again expressed their identity through the foods they choose either to eat or forego.

**SACRIFICE.** Sacrifice is the ritualistic and reverential slaughter, cooking, and distribution of meat. Conventional accounts of sacrifice stress the colorful and religious aspects of slaying an animal for the benefit of the participants' relationships with the gods. This understanding leads to the generalized use of the word "sacrifice" to mean giving up something—including other foods—in anticipation of more valuable rewards.

From the viewpoint of a cultural outsider, sacrifice may seem a brutal or incomprehensible practice. Yet historically, sacrifice has been a common practice in many tribal and agrarian societies, as have food offerings, in a more general sense. Sacrifices serve various functions: the ancient Chinese text *Li chi* describes ceremonies that summon spirits from above to restore social harmony. Maintaining environmental balance is also a common sacrificial motive. Sacrifices are important in the doctrines of Hindus, Jews, Christians, and Muslims: they enable participants to share a table with their deity, give thanks, atone for sins, or appease angry forces. For example, Muslims believe that the animal slaughtered at the Id al-Adha (Festival of Sacrifice) at the conclusion of their pilgrimage to Mecca will carry them to Paradise.

Social scientists have explained that dramatic rituals encourage group solidarity. The act of coming together to present gifts helps to bind members of a group together as well as any blood oath can. According to Scottish anthropologist W. Robertson Smith in *The Religion of the Semites* (1889), sacrifice originated in a meal shared between people and their god. French sociologist Émile Durkheim and his associates asserted that sacrifice constantly renews group consciousness of the sacred and that the all-powerful god which society worships is itself.

Ceremony promotes social cohesion, but such theories are incomplete because they do not explain why cohesion important in the first place. As stated earlier, the underlying action of a sacrifice is the coming together for the slaughter and distribution of meat. This core social action is elaborated on cultural and religious levels. The animal is not lost but is allocated to the group according to precise rules. In groups that perform sacrifices, animals are valuable enough food to warrant special attention, typically at a festival, and often the animals are large enough to warrant wider dispersal than within an imme-

diate household. This dispersal typically takes place at some central place such as a temple.

Early Jewish celebrations of Passover traditionally required the sacrifice of one lamb for each household or for distribution among several small households; the lamb was then eaten with unleavened bread and bitter herbs (Exodus 12:1–28). This ritual is a seasonal festival that, on one level, recalls the nomadic origins of the Hebrews, who would annually gather to celebrate increased flocks. On another level, however, Passover recalls the escape from Egypt after Moses had cursed the Egyptians to suffer the death of their first-born males. To avoid this curse, the Hebrews placed on their door posts a sign made from the blood of sacrificial lambs.

Gods have traditionally played key roles in food distribution. Each temple-state in ancient Mesopotamia had its own deities who lived in the ziggurat and who were fed offerings from the surrounding farms. This tribute not only supported the temple bureaucracy and artisans but also fed the poor of the region. In other places, this type of food redistribution also took place in kingdoms that were under the leadership of warrior rulers. For example, the ancient leader King Solomon oversaw the apportioning of 22,000 oxen and 120,000 sheep at the dedication of his temple. These sacrifices served as a vast round of public meals, which were shared by "all Israel . . . a great assembly" from distant places. These meals also lasted for quite some time, as Solomon dismissed the crowd on the eighth day (1 Kings 8:62–66).

The role of the *mageiros* in ancient Greece also illustrates the social centrality of sacrifice. This same word was used for priest, cook, and butcher (which might bewilder the modern mind). Nevertheless, the common link among these individuals was that each of them was responsible for the cutting up of meat, the priest wielding his cleaver (or *machaira*) ritualistically, the butcher commercially, and the cook artistically.

Aztec priests gained notoriety for sacrificing human victims. In *The Sacred Cow and Abominable Pig*, the anthropologist Marvin Harris argues that such "warfare cannibalism" occurs when captives have greater value as meat than as slaves (pp. 199–234). Yet many claims of human sacrifice are often suspect, as they can be misrepresentations of others as "less civilized." For example,

some people in the ancient world mistook Christians for cannibals because they spoke of their savior as a sacrificial lamb and of their eucharistic bread and wine as his flesh and blood.

Because the acquisition and distribution of meat are so fundamental in society, they have been surrounded by many different relationships, rituals, and meanings. The allocation can become so formalized, the portion of food “lost” to the gods so large, and sacramental feelings so profound that the process may no longer resemble sharing. In addition, many accounts have overemphasized religious meanings at the expense of focusing on the sacrificial process of cooking offerings. However, a gastro-nomic interpretation of sacrifices need not diminish the importance of the ties among people, natural forces, and gods that sacrifices represent. On the contrary, taking the sharing of food under serious consideration arguably grounds the religious aspects of sacrifice and increases their relevance.

In much of the world, the act of slaughtering meat has been removed from plain view to the city outskirts. It has shifted from the butcher’s shop to behind a supermarket wall. The final carving of joints now tends to be kept to the kitchen, and the image of cattle is separate from that of hamburgers. Greater sympathy with ceremonial sacrifice may help reconnect meat-eaters with their metabolic universe. A keener sense of the sacred when eating meat might help counterbalance tendencies toward instant gratification, conspicuous consumption, viewing animals as commodities, and the increasingly unbalanced distribution of the world’s resources. If animal-devouring gourmets do not entirely embrace such religious impulses as atonement, propitiation, divine commensalism, and thanksgiving, they might nevertheless remember that to “immolate”—from the Latin for ‘sacrifice’—is to sprinkle with a condiment.

Arguing for a more materialist reverence that brings the sacred back into the kitchen, Episcopal priest Robert Farrar Capon advises cooks to remember that they inhabit “bloody ground and holy ground at once.” In his recipe book and “culinary reflection,” *The Supper of the Lamb*, he confronts the dilemma of the “bloody, unobliging reciprocity in which life lives by death, but still insists that death is robbery” (pp. 45–52).

**SALAD.** Although the ancient Greeks and Romans did not use the word “salad,” they enjoyed a variety of dishes with raw vegetables dressed with vinegar, oil, and herbs. Pliny the Elder in *Natural History*, for instance, reported that salads (*acetaria*) were composed of those garden products that “needed no fire for cooking and saved fuel, and which were a resource to store and always ready” (*Natural History*, XIX, 58). They were easy to digest and were not calculated to overload the senses or stimulate the appetite.

The medical practitioners Hippocrates and Galen believed that raw vegetables easily slipped through the system and did not create obstructions for what followed, therefore they should be served first. Others reported that the vinegar in the dressing destroyed the taste of the wine, therefore they should be served last. This debate has continued ever since.

The cookery writer Marcus Apicius of the first century C.E. offered several salad recipes, some of which were unusual. His recipe for “bread salad” covers the bottom of a large salad bowl with bread, then adds layers of sliced chicken, more bread, sweetbreads, shredded cheese, pine nuts or almonds, cucumber slices, finely chopped onions, then finishes with another layer of bread. A dressing made of celery seed, pennyroyal, mint, ginger, coriander, raisins, honey, vinegar, olive oil, and white wine is poured over the salad. Another dressing Apicius used on lettuce was a cheese sauce that included pepper, lovage, dried mint, pine nuts, raisins, dates, sweet cheese, honey, vinegar, *garum* (fish sauce), oil, wine, and other ingredients. Other Roman salads were similar to present-day ones, such as lettuce and cucumbers or raw endive dressed with *garum*, olive oil, chopped onion, and vinegar or a dressing of honey, vinegar, and olive oil. Roman salad dressings eventually became more complex. Apicius gave a recipe for one containing ginger, rue, dates, pepper, honey, cumin, and vinegar. With the fall of Rome, salads were less important in western Europe, although raw vegetables and fruit were eaten on fast days and as medicinal correctives.

Many medical professionals did not approve of fresh fruits and uncooked vegetables. Both were considered “cold” in the humoral system of medicine. To counter

this coldness, salads were seasoned with salt and olive oil, which were thought to be “hot,” thus counteracting the coldness of the raw fruits and vegetables. However, this health concern continued into the nineteenth century.

### The Emergence of *Salade*

The term *salade* derived from the Vulgar Roman *herba salata*, literally ‘salted herb’. It remained a feature of Byzantine cookery and reentered the European menu via medieval Spain and Renaissance Italy. At first “salad” referred to various kinds of greens pickled in vinegar or salt. The word *salade* later referred to fresh-cooked greens or raw vegetables prepared in the Roman manner.

Under the category of herbs and vegetables, Platina’s *De Honestæ Voluptate et Valetudine* (1470) included salads, such as raw lettuce seasoned with a vinaigrette composed of olive oil, vinegar, and salt; boiled endive, borage, or bugloss with a vinaigrette seasoned with calamint and mint parsley; purslane with a vinaigrette seasoned with onions; boiled mallow placed in a dish like asparagus and seasoned with a vinaigrette; pimpinell seasoned with a vinaigrette; sorrel served as a first course with bread seasoned with a vinaigrette; and asparagus served in wine. Platina also offered a salad (*pantodapum*) composed of lettuce, borage, mint, calamint, fennel, parsley, wild thyme, marjoram, chervil, sow-thistle, and other herbs seasoned with a vinaigrette and served in a large dish. Common Italian salads of the twenty-first century include *insalata condita*, a green salad; *insalata caprese*, composed of sliced tomato and mozzarella with fresh basil dressed with olive oil; *insalata russa*, composed of cooked vegetables; and *insalata di mare*, a seafood salad.

### French *Salade*

The French cookery manuscript *La Viandier* from the fourteenth century includes a recipe titled “*Poree de Cresson*,” a leek stew, which mutated into a vegetable stew of a soupy consistency. *La Viandier* recommends serving boiled watercress and chard with oil, cheese, meat broth, and salt. In the following century the French sprinkled raw vegetables with oil and vinegar in the Roman manner. François Rabelais (1490–1553) mentioned a long list of *salades*, including ones with cress, hops, wild cress, asparagus, and chervil. In the next century Louis XIV (1638–1715) had a weakness for salads. According to the French culinary historian Maguelonne Toussaint-Samat, in *History of Food* (1992), Louis XIV “ate a prodigious quantity of salad all the year round.” Hygienic precepts of the time held that salads were “moistening and refreshing, liberate the stomach, promote sleep and appetite, temper the ardors of Venus and quench the thirst” (Toussaint-Samat, 1992, pp. 695–696).

Prejudice against raw vegetables and fruit continued, and green salads were not commonly served on the tables of the upper class until the late eighteenth century. Jean-Anthelme Brillat-Savarin, in *The Physiology of Taste* (1986) felt obliged to recommend salads “to all who have

Modern restaurant salads have evolved into studies in the deliberate arrangement of raw plants of different colors and textures. Since the food must be arranged by hand, some food critics have decried this as unnecessary and overly fussy, yet the eye appeal cannot be denied. © AARON REZNEY/CORBIS.

confidence in me: salad refreshes without weakening, and comforts without irritating; and I have a habit of saying that it makes me younger.”

Common French salads include *salades simples*, plain salad composed of raw salads and cooked salads composed of vegetables; *salade andalouse*, cooked rice seasoned with vinegar, salt, and paprika; *salade de légumes*, a vegetable salad seasoned with oil, vinegar, salt, and pepper; *Rossini salad*, truffles dressed with vinegar, lemon juice, salt, and pepper; *salade parisienne*, vegetable salad with lobster or crayfish and truffles dressed with mayonnaise; and *salade Niçoise*, composed of diced potatoes, hard-boiled eggs, French beans, olives, capers, tomatoes, and anchovies dressed with olive oil, vinegar, salt, and pepper. French salads are frequently seasoned with a vinaigrette of oil, vinegar, mustard, salt, and pepper. Anchovies, cream, bacon fat, garlic, lemon juice, egg yolks, paprika, and tomato juice are sometimes added to the vinaigrette.

### English *Salet* or Salad

In the late fourteenth century the English *salade* or *salet* (also *sallet*) was frequently composed of leafy vegetables served as an accompaniment to cooked meats or poultry. *The Forme of Cury* (c. 1390) includes a recipe that calls for parsley, sage, garlic, chives, onions, leeks, borage, mint, cress, fennel, rue, rosemary, and purslane. Other

The construction of the perfect salad was done with great flourish in the nineteenth century; aside from carving meat, it was one of the few food preparation activities allowed to men at table. This much-copied image first appeared in *Salad for the Social* (New York, 1856) by American essayist Frederick Saunders (1807–1902). ROUGHWOOD COLLECTION.

salad recipes included flowers, and later fruits, such as oranges and lemons, were added at least in a decorative role. John Gerard's *Herball* (1597) offered many serving suggestions. As new vegetables, such as sweet potatoes from the Caribbean and red beets from Europe, entered England, they were added to the list of salad ingredients. At first salads were simple compositions, such as sliced lemons with sugar. But these became increasingly complex and could be assembled from many herbs, fruits, nuts, spices, and flowers. In the late seventeenth century the grand *sallet* had multiple ingredients, including borage, capers, carrots, cowslips, currants, marigold, primrose, purslane, violets, and sugar and were dressed with oil and vinegar.

John Evelyn's *Acetaria* (1699; 1982) was the first salad book published in the English language. Evelyn defined *sallet* as "a particular Composition of certain *Crude* and fresh herbs, such as usually are, or may safely be eaten with some *Acetous* Juice, Oyl, Salt, &c. to give them a grateful Gust and Vehicle." He included roots, stalks, leaves, and flower buds but excluded fruit, although the juice and the grated rind of oranges and lemons were listed among the herbs. Evelyn's salads have no meat. His recipe for salad dressing says, "Take of clear, and perfectly good *Oyl-Olive*, three Parts; of sharpest *Vinegar* . . . *Limon*, or Juice of *Orange*, one Part; and therein let steep some Slices of *Horse-Radish*, with a little *Salt*" (Evelyn, 1982, pp. 121–122). But Evelyn banned garlic, although he admitted that Spaniards and Italians used it "with almost everything."

By the early nineteenth century the art of salad making in the French style had been introduced to England

by émigrés who fled to London during the French Revolution. By the mid-nineteenth century salads and their dressings were taken seriously in England. Mrs. Beeton's *Book of Household Management* (1859–1860) includes the first known recipe titled "fruit salad."

### American Salad

Americans had little interest in green salads and most other salads before the Civil War. Some exceptions did exist. German immigrants brought with them hot potato salad, usually made with bacon, onion, and vinegar. The Shakers made fruit salads, which might not include any greens at all. The medical establishment considered raw fruits and vegetables unhealthy and the cause of illness. However, by the mid-nineteenth century the medical profession reversed its earlier opposition to eating raw fruits and vegetables and promoted salads as healthful. Poultry and cooked vegetable salads occasionally graced the American table.

During the 1880s salads joined the culinary experiences of all Americans. The first known American cookbook solely dedicated to salad making was Emma Ewing's *Salad and Salad Making* (1883). At that time molded salads, composed with gelatin or aspic and sugar or sweet fruits, were invented. Salads included such greens as watercress, dandelions, sorrel, chicory, escarole, chives, kohlrabi, and celeriac. Although tomatoes had been used as or in salads for decades, the ubiquitous lettuce and tomato salad first appeared in the United States in the late nineteenth century, when it became one of the more common salads in cookbooks. It was popularized by Fannie Merritt Farmer's *Boston Cooking School Cook Book* (1896). Another common dish was the perfection salad, which was composed of shredded cabbage, diced celery, minced onions, canned pimiento, and chopped olives held together with gelatin, vinegar, lemon juice, sugar, and Worcestershire sauce.

European-style salads were served to the upper class in restaurants in large cities. In New York, for instance, Delmonico's Restaurant specialized in the then novel green salads dressed with vinegar and olive oil. Oscar Tschirky, initially a chef with Delmonico's, moved to the Waldorf Astoria, where he invented the Waldorf salad, a combination of lettuce, apple, and celery dressed with mayonnaise. Walnuts were added in the 1920s. The salads were popular, but the salad dressings were also. The New York restaurateur George Rector noted in *À la Rectors* (1933) that a new salad dressing could become "the talk of the town" and could attract customers away from other restaurants. By the end of the century, salads had found a place in many middle-class homes and restaurants. In *The American Salad Book* (1899) Maximilian De Loup reported that Americans preferred them to "heavy bulky materials," and he believed green salads were the wave of the future.

Beginning in the late nineteenth century, salads were promoted by manufacturers of salad dressings and oils.

Until the passage of the Pure Food and Drug Act in 1906, vinegar and olive oil were frequently adulterated with acetic acid and cottonseed, peanut, rapeseed, and poppy seed oils. To promote their products in the twentieth century, companies composed booklets of recipes for salads dressed with commercial dressings. Early commercial manufacturers of salad dressings included Best Foods, E. R. Durkee & Company, R. T. French Company, H. J. Heinz Company, Richard Hellman, Jell-O Company, Kraft-Phoenix Cheese Corporation, and Tildesley & Company, and those manufacturing oil included Mazola and Wesson Oil. By the 1920s, bottled mayonnaise and salad dressings were commonly used in households across the United States.

Salads flourished where the raw ingredients were easily available, particularly in Florida and California. Francis Harris's *Florida Salads* (1914) was revised and reprinted several times during the early twentieth century. However, California was considered the "land of salads" and salad dressings. Green Goddess Dressing, introduced by the Palace Hotel in San Francisco in the early 1920s, was purportedly inspired by the British actor George Arliss, then performing in the play by that name. In 1926 Robert Cobb, owner of the Brown Derby restaurant in Los Angeles, introduced Cobb salad, which consists of avocado, tomato, watercress, lettuce, bacon, chicken, Roquefort cheese, and a hard-boiled egg arranged in a striped pattern in a flat bowl and topped with French dressing. So pervasive was the California influence on food that the chef's salad became a meal in itself throughout the United States.

Salads arrived in the United States from other countries, continents, and cultures. German potato salad, a cold or hot side dish made with potatoes, mayonnaise, and seasonings, became popular in mainstream America in the second half of the nineteenth century. In the twentieth century Caesar Cardini, an Italian immigrant who opened several restaurants in Tijuana, Mexico, created the Caesar salad with romaine lettuce, garlic, olive oil, croutons, Parmesan cheese, Worcestershire sauce, and often anchovies. The Caesar salad became popular with Hollywood movie people who frequented Tijuana, and it quickly spread to Los Angeles and other cities. Italian immigrants helped popularize the lettuce and tomato salad and introduced cold pasta salads of tortellini, mayonnaise, and dill.

In the late twentieth century, health food advocates championed salads, which were greatly advanced by the invention of the salad bar purportedly by the Chicago restaurateurs Rich Melman and Jerry Orzoff, whose R. J. Grunts featured a long counter of greens, seasonings, vegetables, and condiments. Many restaurants and delis throughout the United States quickly adopted and expanded this concept.

Salad dressings range from simple to elaborate. Three common dressings of the early twenty-first cen-

tury are vinaigrette, commonly called Italian dressing in the United States, composed of three parts oil to one part vinegar; Thousand Island, a mayonnaise-based dressing flavored with chopped tomatoes, peppers, and other ingredients that is presumably named for the small islands in the St. Lawrence River between the United States and Canada; and Roquefort or, more accurately, blue cheese dressing.

**SALMON.** *See* **Fish: Sea Fish.**

**SALT.** Because salt is indispensable to life, acts as a food preservative, and uniquely flavors foods, humans have been preoccupied with it since the beginning of recorded history. The desire to obtain salt politically or militarily has influenced the histories of countries in Asia, Africa, Europe, South America, and the Middle East. Indeed, salt was used as a form of currency and had greater value than gold in some ancient societies. Even religious and magical significance has been attributed to this mineral.

In chemistry, the term “salt” generally refers to any compound that results from the interaction of an acid and a base. In the fields of geology and agriculture, the term “salt” is used as a synonym for the word “mineral.” Although numerous salts are essential to human health (for example, potassium chloride, sodium hydroxide), in the following paragraphs the term “salt” will refer specifically to the inorganic, white crystalline substance that is known as sodium chloride (abbreviated NaCl), unless otherwise noted. It is also known as table salt, rock salt, sea salt, and saline. The reader should be aware that some paragraphs below refer to sodium chloride, whereas others refer to sodium, the mineral/ion/electrolyte.

When sodium chloride enters the body, it dissociates almost completely into its constituent particles, the ions sodium and chloride. Sodium chloride is soluble in water and glycerin. Sodium is the most plentiful ion in blood. As electrically charged particles, positively charged sodium ( $\text{Na}^+$ ) and negatively charged chloride ( $\text{Cl}^-$ ) are classified as electrolytes because they conduct electricity when dissolved in water.

### Dietary Salt

Sodium exists in many foods that are commonly consumed in Western diets including processed sandwich meats, cheese, canned vegetables, pickled foods, salty snacks, and soft drinks. Other sources of sodium are not as well recognized: condiments, sauces, baking soda, baking powder, and bread. In restaurant foods, fast-food meals, and Chinese cuisine the sodium levels can be very high. Only about 10 percent of the sodium in Western diets is due to discretionary salt added at the table.

The sodium content of plants and vegetables depends on numerous factors. These include plant maturity, genetics, agricultural practices, soil salinity, soil fertility, soil pH, the rate at which water percolates through soil, as well as meteorological factors such as rainfall, cloud cover, and sunlight.

For most Americans today, eating preserved and processed foods has become a way of life. Sodium chloride is the most common food additive. Approximately 75 percent of sodium in Western diets originates from processed foods. Because salts of all kinds, including sodium chloride, are very stable, it is virtually impossible to remove sodium from foods that have been canned in glass or metal containers. In fact, the addition of sodium may occur during home meal preparation as well as commercial processes. For example, it is possible that a veg-

etable contains only 2 mg of sodium per 100 g on the vine but may contain 2 to 310 times that amount after canning. Processes such as adding a salt solution to prevent discoloration of vegetables (that is, brining), or the use of sodium salts as processing aids, also result in the addition of sodium to the final product.

### Salt in Food Processing

In the late nineteenth and early twentieth centuries, before modern processing techniques existed, food preservation consisted primarily of heat sterilization used in combination with the addition of salts and spices. Salt was used to suppress the growth of unwanted bacteria. Today, sodium is added to processed foods in several forms. Sodium nitrate and sodium nitrite are added to meats as preservatives. Sodium citrate monobasic is added as a pH buffering agent. Both sodium fumarate and malic acid sodium salt are added to foods as buffering agents and flavor enhancers. These salts are used in concert with numerous other food additives in the United States (for example, antioxidants, stabilizers, colors, sweeteners, enzymes, and emulsifiers), under the direction of the U.S. Food and Drug Administration.

Fergus Clydesdale, a professor at the University of Massachusetts at Amherst, explained in 1988 that the loss of sodium during processing is solely due to leaching (that is, extraction, rinsing, or filtration). Canning, boiling, steaming, blanching, and cooking are the processes most likely to cause leaching of sodium and other salts. However, the extent to which these electrolytes are lost varies with the food product, type of processing, and properties of each ion. The amount of water used in a given commercial process also affects mineral losses. Steaming, for example, uses less water than boiling. Further, the total processing time may affect sodium losses from foods. Brief procedures will likely extract less salt than lengthy ones.

Various other salts (for example, potassium chloride, magnesium chloride, sodium nitrate, sodium benzoate, and sodium acetate) are added to foods during commercial processing. They serve to cure meats, provide or intensify the flavor of numerous products, decrease caking of dry products, stabilize pH (that is, when used with jams, gelatins, baked goods, pasteurized cheese), fortify nutrients, and enhance texture. Sodium nitrite, for example, reacts with meat pigments to develop a characteristic pink color. In bread and baked goods, salt serves a variety of functions including the control of the rate of fermentation in yeast-leavened products. Fermented vegetables such as sauerkraut require salt for flavor and to extract water and other nutrients from the plant tissue to form brine, in which desirable organisms flourish and undesirable ones are subdued. The firmness and color of fruits and vegetables are preserved by the calcium salt of lactic acid. In cheese products, salt is added to the curd or applied to the cheese surface to remove whey and to slow the production of acid. Sorbic acid and its salts are antimicrobial agents that work to suppress the growth of

bacteria; molds in cheese, sausages, fruits, jellies, bread and cakes; and yeasts in salad dressings, tomato products, syrups, candies, and chocolate syrup.

### Biological and Physiological Considerations

The various minerals in the human body serve to maintain acid-base balance, blood volume, and cell membrane permeability, and provide the constituents of bones and teeth. Sodium chloride is important in maintaining the proper concentration of body fluids (that is, osmolality), expediting fluid movement between cells, enhancing glucose absorption, and allowing proper conduction of impulses along nerve and muscle tissues.

Body fluids are distinguished as either intracellular (that is, existing inside muscle and organs) or extracellular (that is, circulating blood plus the interstitial fluid that lies between cells). To accomplish their functions, body tissues maintain intracellular and extracellular ions in different concentrations. This requires considerable energy, approximately one-third of all resting metabolism, and is accomplished by molecules that are embedded in cell membranes throughout the body; these large protein molecules are known as pumps because their action causes an unequal distribution of an ion on the inside and outside of a membrane. In blood, the concentrations for some ions (for example, potassium and calcium) are maintained within narrow limits. Table 1 illustrates these concepts for sodium, chloride, potassium ( $K^+$ ), and magnesium ( $Mg^{2+}$ ). Chloride is the most common negative ion that combines with sodium in the extracellular fluid. Sodium and chloride account for more than 80 percent of all particles in the extracellular fluid. Potassium, magnesium, and phosphate are the most abundant intracellular ions. Potassium speeds energy metabolism and is involved in the synthesis of proteins and a storage form of carbohydrate (that is, glycogen). Magnesium allows the body's chemical reactions and biochemical pathways to function efficiently. Approximately 60 percent of the body's magnesium exists in the skeleton, in combination with calcium and phosphorus; in fact, 99 percent of all calcium exists in bones and teeth. The remaining magnesium is present in red blood cells and muscle, supporting the transport and storage of oxygen.

The concentrations of ions in sweat and urine, which constitute the major avenues of loss, may vary markedly between individuals. This large range exists in sweat and urine because diet, acute exercise, chronic physical training, and heat acclimatization alter the loss of these ions—especially sodium and chloride—at the sweat glands and kidneys.

### Sodium Metabolism

Sodium is so intimately related to other intracellular ions, extracellular ions, and water that it is difficult to consider the factors that regulate its metabolism independently. Nevertheless, the following text is limited to the regulation of sodium retention and excretion.

**TABLE 1**

#### **Sodium, chloride, potassium, and magnesium ion concentrations (mmol/L) in intracellular fluid and in four extracellular fluids**

Source	Sodium	Chloride	Potassium	Magnesium
Intracellular fluid	8	150	31	10
Extracellular fluids				
Sweat	15–53	4–8	2–5	15–70
Urine	32–224	43–60	8–10	39–218
Blood plasma	96–110	3–6	1–2	135–145
Saliva	11–45	11–23	0.1–0.4	10–75

At rest, the kidneys filter circulating blood at the rate of 1.0 to 1.5 L/min, causing the kidneys to generate approximately 180 L of fluid during a 24-hour period. Because the average urine volume of normal adults totals 1.3 L/day, almost all of the renal filtrate is reabsorbed and returned to the bloodstream. The amount of sodium excreted into the urine depends upon the body's need for sodium. If excess sodium is consumed without water, the kidney excretes urine with a high concentration of sodium. If dietary sodium is restricted, the kidneys are capable of producing a dilute urine that maintains the concentration of sodium in body fluids at a normal level.

Whole-body sodium balance is maintained over a wide range of dietary and environmental conditions, primarily due to the action of the hormone aldosterone on the kidneys. When dietary sodium is high, urinary sodium increases to excrete the excess. When dietary sodium is low, aldosterone reduces the loss of sodium in urine appropriately. Thus, a sodium deficiency is rare, even among individuals who consume very low-sodium diets (see below). The body may experience a sodium deficiency when sweat losses are large and persistent, or when illness (for example, chronic diarrhea, renal disease) results in inadequate sodium retention by the kidneys. Following major changes in dietary sodium levels, concentrations of the following hormones also adapt, suggesting that they minimize perturbations of extracellular fluid-ion balance: renin, angiotensin II, atrial natriuretic peptide, and nitric oxide. The latter compound plays a pivotal role in blood pressure maintenance by regulating sodium and water excretion at the kidneys. Despite our knowledge of these facts, scientists cannot explain the exact mechanism by which the brain assesses whole-body sodium status.

A predictable sequence of events occurs when a normal individual limits the intake of sodium (for example, 230 mg daily). During the initial days of salt restriction, urinary sodium levels progressively decrease until about the fifth day, when the 24-hour losses become small (for example, 115 mg or less). This individual ordinarily loses 1 or 2 kg of body weight, which is attributable to the loss of sodium and an appropriate volume of water. Initially,

the reduced body water comes almost exclusively from the extracellular fluid; as time passes, the intracellular fluid compartment also shrinks. For the next few days, urinary sodium concentration remains low, and the body continues to maximize salt conservation until a reduced whole-body sodium equilibrium is established. Sweat sodium levels decrease in a manner similar to urine during dietary restriction; both are due to the action of the hormone aldosterone.

### Toxicity

As is true for virtually all nutrients and compounds, salt can be detrimental or lethal in large quantities. Direct contact with sodium chloride can cause skin irritation, and heating it to high temperatures emits a vapor that irritates the eyes. When heated to the point of decomposition, it emits toxic chloride and disodium oxide ( $\text{Na}_2\text{O}$ ) fumes. When consumed in large amounts, sodium chloride can cause stomach irritation. In addition, laboratory experiments have shown the following dose-response effects: 50 mg/24 hr, skin irritation in rabbits; 100 mg/24 hr, moderate eye irritation in rabbits; 125 mL, inhibition of DNA synthesis in isolated human cells; 27 mg/kg body weight, abortion of a human fetus; and 3,000 mg/kg body weight, lethal oral dose for 50 percent of the animals tested. Potassium chloride causes physiological responses at the following doses: 500 mg/24 hr, mild eye irritation in rabbits; 125 g/L, lung cell death in hamsters; 2,600 mg/kg body weight, lethal oral dose for 50 percent of the animals tested. Calcium chloride is lethal for 50 percent of the animals tested at a dose of 1,000 mg/kg body weight, when administered orally, and at an intraperitoneal dose of 264 mg/kg body weight. Studies have shown that magnesium chloride is lethal for 50 percent of rats tested at an oral dose of 2,800 mg/kg body weight.

The preservatives known as sulfites (see Sodium and Hypertension, below) can produce deleterious side effects, when consumed in large quantities. Investigations involving laboratory animals have shown that sulfites may inhibit some of the body's biochemical reactions and retard whole-body growth in infants; cause gastrointestinal distress; and induce reversible anemia, nutrient deficiency (for example, thiamine), and gene mutations. A lethal oral dose of sodium bisulfite (50 percent of the animals tested) was 498 mg/kg body weight in rats and 300 mg/kg body weight in mice.

Monosodium glutamate (MSG) is added to foods by chefs to potentiate various flavors. This effect is greatest in meat- and vegetable-based soups, sauces, gravies, and spice blends. The levels of MSG in foods range from approximately 0.3 percent in spinach and tomatoes to about 10 percent in parmesan cheese and 20 percent in dehydrated soup mixes. Some consumers also mix additional MSG into foods in the form of sauces. This may be strongly influenced by cultural food preferences. In Korea and Taiwan, for example, the average adult consumes

six to ten times more MSG each day than the average person in the United States. Because sodium is a part of the molecular structure of MSG, it becomes available as free, metabolically active sodium. Therefore, individuals who consume restricted-sodium diets (see Sodium and Hypertension, below) should monitor both the natural levels of MSG in foods as well as the amount that is intentionally added. Monosodium glutamate also produces unwanted side effects in some individuals, including warmth, tingling, tightness, headache, swelling of the liver, and a feeling of pressure in the upper body or face. This phenomenon is often associated with consumption of Chinese food because of its high MSG content. The toxicity of MSG has been studied extensively and it is relatively low, compared to other salts. It has been estimated, for example, that an average adult, weighing 70 kilograms, would have to consume more than 3 pounds of MSG at one time to experience a toxic effect. This does not mean, however, that detrimental effects are nonexistent. A large quantity of MSG has been associated with convulsions, vomiting, and nerve cell damage in research animals, although there are great differences between species. Studies have shown that MSG is lethal, for 50 percent of rats tested, when consumed as an oral dose of 17,300 mg/kg body weight. Thus, when consumed in typical amounts, MSG does not appear to induce illness or toxicity. Because the scope of this article does not allow detailed considerations of the toxicities of other salts, the reader may refer to the book *Food Additive Toxicology* for further information.

### Sodium and Hypertension

Because the kidneys regulate the volume of circulating blood, they are intimately involved in the genesis of high blood pressure (that is, hypertension). This disease often involves excessive retention of extracellular fluid, especially in the bloodstream. For unknown reasons, resistance to blood flow through the kidneys is increased two- to fourfold. And, unfortunately, even though blood pressure may be reduced by prescription medications, the kidneys do not excrete normal amounts of salt and water in urine. This scant urine output causes water and sodium retention until blood pressure rises again to an elevated level. Treatment for this fluid and electrolyte retention often involves diuretics, which increase hourly water and salt losses in urine markedly. Considering these facts, a multiple-stage scientific hypothesis has evolved. This concept proposes that a high dietary sodium intake (1) overloads the kidneys' capacity to excrete sodium and results in fluid retention, (2) increases endocrine gland secretion (that is, natriuretic hormone), (3) inhibits cell membrane function, (4) increases the sodium concentration inside cells and calcium levels in the smooth muscles that encircle blood vessels, which (5) subsequently increases the resistance to blood flow and blood pressure. Interestingly, some research indicates that hypertension may be dependent on the coexistence of sodium and chloride in the diet. Consumption of chloride salts (for ex-

ample, potassium chloride and calcium chloride) is associated with hypertension, in a way similar to that of sodium.

Forty-three million Americans live with persistently high blood pressure, defined as readings of 140/90 mm Hg or above; this represents 24 percent of the adult population of the United States. This makes it one of today's most prevalent disease conditions. High blood pressure increases the risk of stroke, heart disease, and kidney failure. Individuals with a family history of hypertension, the elderly, middle-aged men, and middle-aged black women are at greatest risk. Yet, everyone is vulnerable because blood pressure typically rises with age.

It is important to acknowledge that heredity plays a critical role in hypertension and that this complex disease is affected by many different genes. Present wisdom states that, without these genes, a person will not develop high blood pressure. Such individuals, whose blood pressure increases with increasing sodium consumption, are salt-sensitive. This explains why there are great differences in human responses to sodium chloride.

Several factors play a role in reducing high blood pressure. In hypertensive adults, for example, a single aerobic exercise session (45 minutes) reduces blood pressure for 12 to 24 hours. A healthy diet (high in fruits, vegetables, low-fat dairy products; low in saturated and total fat) also reduces blood pressure. But salt has received the most attention. There is a large body of evidence, and consensus within the scientific community, that dietary sodium chloride is a risk factor for high blood pressure, independent of other risk factors such as alcohol and obesity. During the last 25 years, numerous professional organizations and advocacy groups have supported reductions of sodium in commercially processed foods, including the American Academy of Pediatrics, American College of Cardiology, Food Research Action Center, American College of Preventive Medicine, American Health Foundation, National Alliance of Senior Citizens, and National Urban Coalition.

In countries where dietary sodium is low, high blood pressure is rare. According to clinical investigations, when hypertensive adults reduce salt consumption their blood pressure usually decreases, although not always to a normal level. Additional evidence suggests that a high-salt diet aggravates other illnesses including asthma, gastric cancer, kidney stones, and osteoporosis. Therefore, consuming a low-salt diet will, for many people, reduce their risk of developing or aggravating a chronic illness such as cardiovascular stroke.

Individuals who are placed on sodium-restricted diets often consume other salts in place of sodium chloride. This increases the daily potassium intake because salt substitutes usually contain a high percentage of potassium chloride. This dietary strategy offers potential health benefits in the form of lowered blood pressure and reduced risk of stroke. For some individuals, however,

## TWO LOW-SODIUM RECIPES

The April 1985 issue of *FDA Consumer* magazine provided two recipes as examples of low-sodium meal items that are easy to prepare. The first describes baked dinner rolls and yields 100 servings: 3¼ ounces active dry yeast, 2 quarts water, 7¼ pounds all-purpose flour, 1⅓ cups sugar, 1 tablespoon salt. Normally, a recipe of this size would utilize 4 tablespoons of salt, resulting in a sodium content of 295 mg in each roll. By reducing the amount of salt by 25 percent, each roll contains only 73 mg of sodium.

The second recipe describes low-sodium sausage patties and yields 16 servings. Mix 1 pound ground beef with 1 tablespoon lemon juice, ¼ cup dry bread crumbs, ¼ teaspoon sage, ¼ teaspoon ginger, 1 teaspoon garlic powder, 1 teaspoon onion powder, and ½ teaspoon liquid smoke. Dissolve 1 low-sodium bouillon cube in water and add this solution to the ground beef mixture. Mix thoroughly and let stand for 15 minutes. Form sixteen 1-ounce patties. Brush skillet with vegetable oil and cook the patties for seven to eight minutes on each side, or modify the time as desired. The use of low-sodium bouillon is the key to sodium reduction in this recipe.

the use of a potassium-containing salt substitute can cause illness or death. Individuals with a disease, those taking medications, and the elderly should be advised that these salt substitutes ought to be used only to enhance taste, and not for cooking purposes. Sulfites also should be considered. These compounds preserve food by retarding deterioration, rancidity, or discoloration and thus are categorized as antioxidants. At least three sulfites are commonly used as food additives: sodium sulfite ( $\text{Na}_2\text{SO}_3$ ), sodium metabisulfite ( $\text{Na}_2\text{S}_2\text{O}_5$ ), and sodium bisulfite ( $\text{NaHSO}_3$ ). Because these preservatives contain sodium that becomes free and metabolically active in cells, each contributes to the diet's total sodium load.

Unfortunately, reducing the salt content of foods, to restrict sodium consumption, affects the quality and properties of foods. In the meatpacking industry, for example, reducing sodium chloride extremely results in inferior meat cohesion and water retention, and reduces shelf life. These and other unwanted effects explain why commercial food processors usually do not reduce the sodium chloride levels in their products voluntarily.

### Managing Dietary Sodium

Compared to the average daily intake in the United States, ranging from 2,300 to 6,900 mg/day, the minimum

physiological need for sodium (40 to 300 mg/day) and the intake necessary for good health (500 mg/day) are very small. In fact, the amount of sodium in fresh vegetables alone may be enough to meet an adult's basal requirement. Eight simple procedures make reducing salt intake effective. First, cook with only small amounts of added salt. Second, add little or no salt to food at the dinner table. Third, limit your intake of salty foods such as potato chips, salted nuts, pretzels, popcorn, soy sauce, steak sauce, garlic sauce, pickled foods, and cured meats. Fourth, request that the chef omit salt from your restaurant meal. Fifth, educate yourself about foods that contain large quantities of sodium and seek low-sodium brands when shopping for crackers, pasta sauce, canned vegetables, bread, and other commercial products. Sixth, develop a taste for the unsalted flavor of foods. The taste preference for salty foods can be altered with patience. Seventh, evaluate your diet by reading food labels carefully to determine the sodium content. This can be especially helpful in the aisles of a supermarket because you cannot eat what you do not purchase. Eighth, make a mental list of foods that you will avoid because they contain too much sodium. Here are a few examples, presented in units of milligrams per 100 g of food: fried crisp bacon, 2,400; baking soda, 9,000; beef bouillon cube, 24,000; bologna, 1,300; celery salt, 28,000; cured ham, 1,100; dill pickle, 1,400; frankfurters, 1,100; salt pork, 1,800; green pickled olives, 2,400; and processed cheese, 1,500.

Careful selection of low-sodium food items also will prove to be useful. Table 2 provides a comparison of the sodium content of several vegetables, in fresh and canned forms. Obviously, individuals who desire to reduce their total dietary sodium levels should substitute fresh vegetables for canned varieties, whenever possible. The exception to this recommendation lies in vegetables that lose sodium during processing, due to leaching. This provides the added benefit of ensuring that other dietary nutrients are not lost during commercial packaging (that is, leaching, boiling, blanching).

Another excellent way to lower sodium intake is to alter food preparation practices in the home. Many spices, herbs, and other flavorings do not contribute significant amounts of sodium but may be used to improve the flavor of low-sodium meals. These include allspice, basil, bay leaf, chives, cinnamon, cloves, curry, dill, garlic, ginger, leeks, lemon juice, mint, mustard, nutmeg, orange extract, oregano, paprika, parsley, pepper, peppermint, pimento, poppy seed, saccharin, saffron, sage, sesame, brown and white sugar, tarragon, vanilla extract, and wine.

In determining the amount of sodium that a person consumes, groundwater is often ignored. However, the sodium content of public and private aquifers in the United States varies greatly from one location to another. Although most sources of water include less than 20 mg of sodium per liter, a minor input to daily sodium, certain areas of Arizona, Texas, and Illinois report 325 to

**TABLE 2**

**Sodium content (milligrams per cup) of vegetables:  
Fresh versus canned**

	Fresh, raw	Canned
Asparagus	4	285
Beets	57	36
Carrots	31	280
Green beans	8	536
Green peas	2	236
Lima beans	1	310
Sweet potatoes	24	48
Tomatoes	2	18
Tomato juice	2	230

432 mg of sodium per liter of groundwater. Considering the fact that the average adult consumes more than 2 L of fluid each day, this could mean that some Americans receive over 1 g of sodium per day from tap water alone. If a water softener is used to reduce hardness from a local water supply (for example, remove the mineral calcium carbonate), sodium content can be magnified.

Individuals on low-salt diets also should be concerned about the adequacy of other nutrients. It has been estimated that 40 percent of all low-sodium diets lack other essential nutrients, especially protein, the B vitamins, riboflavin, and calcium. These deficiencies result from the removal of food items that contain sodium.

### **Salt Restriction and Sodium Deficiencies**

As noted above, the basal physiologic need for sodium is 40 to 300 mg/day and the amount recommended for good health is 500 mg/day. Field studies, conducted between 1931 and 1962, confirmed that adults can eat low-sodium diets and remain healthy. Interestingly, some of these populations lived in tropical climates, where sweat losses were great, including the vigorous Masai warriors of Africa who consume less than 1,955 mg of sodium per day, the inhabitants of tropical Nigeria who ingest less than 2,760 mg of sodium per 24-hour period, and Galilean naturalists who ingest only 736 mg of sodium per day.

It is difficult to deplete the body of sodium. The action of the hormone aldosterone on the kidneys, and the relatively large per capita daily intake of sodium in Western diets relative to basal physiological needs, are quite adequate to maintain whole-body sodium levels. Thus, sodium deficiencies are rare, but may be experienced in three extraordinary situations. The first involves dietary salt restriction as therapy for disease (for example, hypertension or congestive heart failure). The possibility that sodium depletion may occur in these illnesses does not contraindicate the use of a low-sodium diet when suitable, but it is important that the patient be monitored carefully. Frequent measures of serum sodium concentration are desirable during the first few weeks of a salt-

restricted diet. A decline in serum sodium level should prompt a reevaluation. The second circumstance involves diseases of the kidneys or endocrine glands that alter normal sodium balance, such as Addison's disease or diabetes insipidus. The third situation, involving hot environments, is considered in the following section.

Hot Environments Exaggerate Salt Losses

Exercise or labor in cool environments increases the sweat loss and water intake, but the psychological drive to drink and fluid-electrolyte hormones regulate total body water within +0.2 percent (+150 g) of the normal body weight each day. Blood plasma volume is regulated within + 0.7 percent (+ 25 g) on consecutive days.

During mild-to-moderate intensity exercise in a hot environment, voluntary water intake does not keep pace with water losses. Most humans produce 0.8 to 1.3 L of sweat per hour, but replace only one-third to three-fourths of this amount by drinking. Thus, if exercise in a hot environment is prolonged and strenuous, a 3 to 5 percent body weight loss can occur. This is significant because, at these levels, both endurance and strength decline.

Table 1 demonstrates that sweat contains sodium, chloride, and other minerals. In fact, sweat contains more than forty distinct organic compounds. Regarding the sodium chloride content, considerable interindividual differences exist among healthy adults. Physically fit athletes who are heat-acclimatized (that is, adapted to exercise in a hot environment) usually lose 400 to 800 mg of sodium chloride per liter of sweat. In contrast, the sweat of unfit, nonacclimatized adults contains from 1,000 to 3,000 mg of sodium chloride per liter. This difference occurs because physical training and heat acclimatization reduce the concentration of salt in sweat.

Salt Balance during Exercise and Labor

Table 3 provides estimates of the amount of fluid and salt lost in sweat, during different activities that are conducted in hot environments. Obviously, water and sodium chloride losses increase in proportion to the duration and the intensity of exercise. As a point of reference, Table 4 describes selected nutrients that are consumed by an adult in the United States. The intake of sodium chloride averages 4,600 to 12,700 mg, and water consumption averages 2.5 L/day. Comparing these two tables, it becomes obvious that 30 minutes of mild gardening produces a small fluid and sodium loss that can be replaced by a normal diet. An ultramarathon, requiring 20 to 30 hours to complete, involves extraordinary salt (14,400 to 70,000 mg NaCl) and water (18.0 to 35.0 L) losses that far exceed normal 24-hour food consumption. Clearly, constant fluid-electrolyte intake is required, during and after an ultramarathon, to replace lost nutrients.

Three fluid-electrolyte disorders involve sodium (that is, heat exhaustion, heat cramps, and exercise-related hy-

TABLE 3

The amount of water and sodium chloride lost in sweat during labor or during exercise in hot environments		
Event, Duration, Personal Characteristics	Total Water Loss (L)	Sodium Loss (mg) <sup>a</sup>
Mild gardening, 30 min, sedentary adult	0.3–0.5	240–2,000
Strenuous work, 60 min, experienced laborer	0.8–1.5	640–4,500
10-km run, 40 min, healthy adult	0.5–1.0	400–4,000
Leisure hike, 2 hr with rest, heat-acclimatized adult	2.0	1,600–6,000
Intense cycling, 2–4 hr, physically-fit cyclist	3.0–8.0	2,400–24,000
Ultramarathon, 20–30 hr, highly trained runner <sup>b</sup>	18.0–35.0	14,400–70,000

<sup>a</sup>Loss in sweat and urine; these calculations assume a range of 800–4,000 mg sodium chloride per liter of sweat; physical training and heat acclimatization increase a person's sweat rate but decrease the sodium content of sweat and urine.

<sup>b</sup>Running pace is slow and includes walking.

ponatremia) and have become the most common illnesses among athletes and laborers in hot environments. Heat exhaustion, an inability to continue exercise in the heat, is primarily a fluid depletion disorder in which either large sodium, water, or mixed sodium-water losses occur during exercise-heat exposure. Heat cramps occur most often in the abdominal wall and large muscles of the extremities and are due to whole-body sodium depletion. Treatment for these two heat illnesses involves replacing the sodium chloride and water that was lost in sweat and urine. Exertional hyponatremia involves a reduced serum sodium concentration (<130 mEq/L) and represents a marked dilution of the extracellular fluid. This disorder, unlike the previous two, involves overhydration. Athletes

TABLE 4

Consumption of selected nutrients in the United States (mg per day), as published by the National Research Council in 1989.	
Mineral	Amount consumed (mg/day) <sup>a</sup>
Sodium chloride	4,600–12,700
Sodium	1,800–5,000
Potassium	2,500–3,400
Magnesium	207–329
Calcium	530–1,179

<sup>a</sup>The water intake of a 70-kg adult is approximately 2.5 L/day, in solid foods and fluid.

Salt jar made at the Schofield Pottery, Penrith, Cumberland, England, circa 1930. This traditional form, dating to at least the 1600s, was intended for use near the open hearth, where it hung from a hook. ROUGHWOOD COLLECTION. PHOTO CHEW & COMPANY.

or laborers, who consume and retain a large volume of pure water (for example, 10 L in 5 hr), may experience a life-threatening series of physiological changes that signal water intoxication. The most serious effects are coma, fluid in the lungs (pulmonary edema), and brain swelling (cerebral edema).

### Replacing Salt Losses due to Exercise

Individuals who exercise for more than two hours, and who are not hypertensive, should increase their salt intake slightly (see Table 3). Similarly, if a weight loss of 3 percent or more is due to fluid losses during work or exercise, a minor sodium deficit should be expected. The simplest means to replace these deficits after exercise involve adding salt to your meals and selecting saltier foods. Canned soup, for example, contains 1,950 to 2,450 mg of sodium chloride; canned tomato juice contains 1,525 mg. Fluid-electrolyte replacement beverages contain 150 to 300 mg, and 1 percent low-fat milk contains 300 mg sodium chloride. It also is wise to eat more fruits, such as bananas and watermelon, to replace lost potassium.

**SANDWICH.** The bread-enclosed convenience food known as the “sandwich” is attributed to John Montagu, fourth earl of Sandwich (1718–1792), a British statesman and notorious profligate and gambler, who is said to be the inventor of this type of food so that he would not have to leave his gaming table to take supper. In fact, Montagu was not the inventor of the sandwich; rather, during his excursions in the Eastern Mediterranean, he saw filled pita breads and small canapés and sandwiches served by the Greeks and Turks during their mezes, and copied the concept for its obvious convenience. There is no doubt, however, that the Earl of Sandwich made this type of light repast popular among England’s gentry, and in this way, his title has been associated with the sandwich ever since. The concept is supremely simple: delicate finger food is served between two slices of bread in a culinary practice of ancient origins among the Greeks and other Mediterranean peoples.

Literary references to sandwiches begin to appear in English during the 1760s, not only in connection with their presumed Englishness, but also under the assumption that they are a food consumed primarily by the masculine sex during late night drinking parties. This connotation does not change until the sandwich moves into general society as a supper food for late night balls and similar events toward the end of the eighteenth century.

That sandwich, the creation of caterers, is amply described by Louis Eustache Ude, an illustrious cook who finished his career as chef de cuisine of the Crockford Club in London, in his *French Cook* (1818). Ude took particular care to outline a proper supper and the critical execution of the superior sorts of English sandwich that originally gave the food its high status. He explained that bread for sandwiches filled with salads must be specially baked in molds so that the texture is dense, though the crust not dry, to avoid sogginess once the sandwiches are stacked on a silver tray, as they should not bend when held in the hand. Breads for other sandwiches should be baked long and round like a tube so that the slices are even and thus fit neatly together without lumpiness or air spaces between. Furthermore, all crusts on sandwich breads should be rasped so that they acquire the texture of chamois. His sandwiches for two or three hundred persons included fillet of guinea fowl with cold béchamel sauce (“make them towards nine o’clock to serve up at twelve”), fillet of pheasant poached in a fumet, fillet of sole à la Ravigotte, salad sandwiches made of small lettuces and cresses (“cut the salad off which protrudes . . . observe much neatness in the preparing of these sandwiches and do not confide them to any of the kitchen

John Montague (1718–1792), the Earl of Sandwich, whose title is now the name of a popular food. From an eighteenth-century engraving. © CORBIS.

maids.”) And finally, anchovy sandwiches: “the pieces of anchovy should not touch each other, as they might then be too salt, unless when eaten to assist wine drinking.”

Charlotte Mason was one of the first English cook-book authors to provide a recipe for sandwiches, which she published quite appropriately along side other supper dishes like Welsh rarebit and salmagundi (an elaborate ornamental salad): “Put some very thin slices of beef between thin slices of bread and butter; cut the ends off neatly, lay them in a dish. Veal and ham cut thin may be served in the same manner.” Her homey recipe is quite different from the sort of grand fare sent up by the likes of Ude, but far more typical of what happened to the sandwich in the hands of Victorian home cooks.

During the nineteenth century, as midday dinner moved later and later into the day, the need for a hot supper declined, only to be replaced with light dishes made of cold leftovers, ingredients for which the sandwich proved preeminently suitable. Thus the sandwich became a fixture of intimate evening suppers, teas, and picnics, and popular fare for taverns and inns. This latter genre of sandwich has given rise to multitudes of

working class creations, such as the *butty* and *sarny* of Britain, and the *bacon-lettuce-and-tomato* sandwich of the American diner. In the home, however, for such meals as English high tea, or the late-night Quaker “tea” parties of nineteenth-century Philadelphia, sandwiches were not usually premade, but rather, sliced bread was provided, enabling diners to assemble a sandwich from the various tidbits laid out for the meal.

Cookbook author Eliza Leslie was one of the earliest American writers to publish sandwich recipes in the United States. Her *Directions for Cookery* (1837) contained a recipe for what has become a ubiquitous American institution: the ham sandwich. Her sandwich consisted of thinly sliced bread spread with butter and mustard (French mustard flavored with tarragon), and sliced or finely chopped ham, with no other embellishments. “You may either roll them up, or lay them flat on plates. They are used at supper, or at luncheon.” The fact that they needed explanation at all may be taken as a sign of their uncommonness outside of urban centers, since the sandwich of the 1830s was still more or less a creature of upper-class cookery; Leslie’s use of French mustard gives further evidence of that fact.

During the early years of the railroad, sandwiches proved an ideal form of fast food, especially since they could be sold at train stations when everyone got off to buy snacks. With the appearance of the dining car, the sandwich became a travel-related institution, and it remains so as the typical meal served as lunch on airplanes. During the late nineteenth and early twentieth centuries the sandwich came into its own, especially as a response to the Temperance Movement. Taverns and saloons offered free sandwiches with drinks in order to attract customers, which led to the development of many distinctive sandwiches that have endured. In the United States, these include the club sandwich, a multi-layered affair designed to combine two or three types of sandwich into one, a meal in itself, which earned its name through its popularity with businessmen in private dining clubs.

Among working-class men, the submarine loaf became a popular vehicle for hearty sandwiches made with various fillings. This long, narrow Viennese loaf first appeared in the early 1880s as a marketing gimmick in connection with the Gilbert and Sullivan operetta “H. M. S. Pinafore,” which features a ditty with sexual innuendos about submarines. The sandwiches made with this type of bread bear different names in different parts of the country: subs, grinders, poor boys, torpedoes, and hoagies, all featuring very localized types of ingredients. For example, the Philadelphia hoagie (derived from “hokey-pokey man,” the sandwich vendor), contains the essentials of a southern Italian antipasto, including cold cuts, Italian cheeses, peppers, olive oil, and oregano. New England gave birth to the lobster roll: cold, cooked lobster served with mayonnaise in a small toasted submarine loaf (which evolved into hot dog rolls). A hot counterpart to this, the so-called *beefsteak sandwich*, was first popular

in the nineteenth century as fried chipped beef and onions served over toast. Once married to the submarine loaf, it further evolved with the addition of cheese and various hot pepper sauces.

Luncheonettes of the 1920s served grilled cheese sandwiches and the Cuban sandwich, which resembles a hoagie pressed between two hot irons so that it is slightly flattened and hot when eaten. In spite of its association with Havana, this sandwich was created in New York and New Jersey. The most famous of the American hot sandwiches, however, is the Reuben, which was introduced at Reuben’s Restaurant in New York City (there was also a branch in Miami, Florida). The restaurant was essentially a Jewish-owned sandwich shop that offered a wide range of creations named after famous personalities of the 1930s and 1940s: Danny Kaye, Hedda Hopper, Judy Garland, Ozzie Nelson, to name just a few. The Reuben Special, the hot grilled sandwich of fame, contained turkey, Virginia ham, Swiss cheese, cole slaw, and Russian salad dressing. The substitution of pastrami and sauerkraut came later, as a courtesy to kosher Jewish customers, who could not eat ham or a mixture of meat and cheese. Reuben also sold steak sandwiches for \$2.00 (the most expensive sandwich on the menu), a specialty called Chicken Reubenola, and hamburgers on a roll.

The hamburger, at one time simply a meat patty eaten with bread and gravy, has, in the hands of McDonalds and similar global food chains, become the ultimate industrialized food eaten throughout the world, as well as a dubious symbol of American culture in far-off places. While the Earl of Sandwich might not recognize his finger food thus transmogrified and chef Ude might be appalled by the sloppiness of its presentation, neither could find fault with the hamburger’s convenience or its cross-gender, cross-cultural, cross-generational appeal.

**SAUCES.** Sauces are food preparations with a fluid consistency, often with nutritional richness and a relatively pronounced taste, that are used to complement other foods. Although they typically stand out as a special development of cookery, their social and historical importance tends to be underrecognized.

Sauces may be divided into two broad categories. First, they can be essentially nutritious partners to a staple, such as the sauces eaten with pasta, corn chips, rice, and so on. Historically, this group arrived with settled society, when communities relied on perhaps only one cereal (such as barley, wheat, rice, or maize) or tuber (potato, taro, yam, or cassava). These foods could be cultivated in bulk and stored from one crop to the next. However, they were starchy foods that were nutritionally incomplete, requiring the addition of vegetables, legumes, meat and other animal products, often cooked separately as a sauce.

A second category primarily imparts flavor and is often served separately on, or in addition to, meat and vegetables rather than the staple cereal or tuber. These sauces range from relishes, such as tomato ketchup, which are often preserved, to subtle compositions often based on stocks and egg emulsifications and slightly sticky to form a coating. Because they are so refined and velvety, sauces became the pride of French cooking. Just as the first category of sauces catered to the culinary needs of civilization, the second brought to dining a certain luxury and high standard of taste.

Sauces are not normally eaten by themselves, generally require some sort of preparation (a raw ingredient, such as poured cream, is not conventionally considered a sauce), often have a homogenous look and texture, and are usually soft or runny in consistency. However, the boundaries are blurred, variations are many, and language is imprecise.

Some sauces merge with soups and stews, which differ in that it is possible to eat either alone. On the other side of the spectrum, some sauces merge with relishes and condiments. A fluid state is normal, although many pounded compositions are considered sauces (e.g., Italian *pesto* consisting of basil, Parmesan, garlic, and olive oil), and chopped ingredients often act like sauces. For example, pizza toppings are virtually identical to pasta sauces. Although sauces are usually placed on top of other foods, they can also bind other ingredients or function as fillings, encased in buns, pastry packets, sheets of pasta, rice balls, and so on. While the range includes sweet toppings (such as chocolate sauce), soft, sweet pastry fillings are more likely to be called creams or crèmes. Runny custard (*crème anglaise*) can be a sauce, but usually not a set custard or ice cream. Nonetheless, one's definition of the "sauce" category should be flexible, especially for sauces that fill the two roles already described, namely, as a nutritional complement to a staple, or a taste complement to a nutritional complement.

## Reasons for Sauces

The role of sauces may be hedonistic; they are clearly designed to be pleasurable. A more disparaging view is that sauces simply exist to make people overeat, and such an assumption lies behind the familiar saying, "hunger is the best sauce" (perhaps first used by Cervantes in *Don Quixote*). Yet another line of argument suggests that certain sauces are used repeatedly within a cuisine to mark a food as familiar and generally "safe," so that cultural knowledge replaces the eaters' own instincts.

In a more specialized sense, sauces may put the salt back into cooked food from which it was leached. The modern words "sauce," "salsa," and so on derive from the Latin word *sal* for 'salt', which highlights the fact that many sauces have frequently been too salty, often as a result of added ingredients that have been preserved with salt.

Apart from any of this, sauces' historical origin was as a nutritional accompaniment to complex carbohydrates. The ancient Mesopotamian, Egyptian, and Chinese civilizations, and subsequent ones, were based on basic agricultural products, the progenitors of wheat and barley, and so on. In all cases, these staples were complemented by what might, broadly, be termed "sauces." Accordingly, the Chinese speak of supplementing *fan* with *ts'ai*, that is, supplementing cereal and starchy dishes (porridge, steamed rice, dumplings, pancakes, noodles) with vegetables, meat, or fish. The two have to be in balance, although more *fan* might be prepared for everyday meals and more *ts'ai* for feasts. Many of the *ts'ai* preparations are recognizable sauces, served in separate dishes or contained within the staple, such as pork buns.

An Indian meal is focused on a bowl of rice (in the south) or bread (in the north), surrounded by small bowls of vegetables, extra ingredients such as lentils, and possibly meats. These are typically cooked with a careful blend of spices and herbs to make what is called a *masala*, and the best known is *garam masala* from the north. Particularly in southern India, where a more liquid stew better accompanies a larger portion of rice, a wet *masala* is made by adding yogurt, coconut milk, and other liquids. English "curry"—which is based on *Tamil kari*, a sauce in which meat, fish, or vegetables are stewed—often results from the addition of a dry powder by the same name, but this is a mere caricature of the richer, more flavorful Indian curry sauces, which vary depending on the cook's social status, religion, and geographical location.

Foods to accompany staples have often been preserved. Among the various cheeses, dried fruits, pickles, and other relishes that fall in this category, many are readily classified as sauces. Fermented fish sauce, known as *garum* or *liquamen* to the ancient Romans, appears in Asian variants, such as Vietnamese *nuoc mam*. Soy sauce is a similar product (made from fermented soya beans), and Worcestershire sauce is a commercially successful English variant. Bottled sauces have become important, too, notably any kind of tomato sauce.

Bain-Marie or water bath for keeping prepared sauces hot. From a wood engraving, circa 1880. ROUGHWOOD COLLECTION.

Some of the sauces just mentioned are used more for their spicy or pungent flavor, rather than any nutritional value. Such flavorings can be considered a second category of sauces, often refined from the original more nutritious versions.

### Kinds of Sauces

The primary sauces are pounded, stewed, stock-based, starch-thickened, emulsified, preserved, or sweet (which includes custards, syrups, and fruit purées).

**Pounded.** The mortar and pestle have been successfully used to produce an enormous variety of pastes across the globe, including the Italian *pesto* and Indian *masala* already mentioned. Purées, such as tomato sauce, are rubbed through a sieve or finely chopped in a food processor.

**Stewed.** Cooking meat, vegetables, legumes, and/or herbs in a pot with water or other liquid can produce soups, stews, and also sauces. An important example is the Italian accompaniment to *pastasciutta*, the meat *ragù* or *sugo*, known elsewhere as *bolognese* sauce. The *mole* sauces from Mexico are cooked mixtures of many ingredients, including chili and chocolate in the famous *mole poblano* used with turkey.

**Stock-based.** The roasting or baking pan may be deglazed (residues scraped up with liquid and then reduced) to provide gravy. Much more important, the *fonds* (“foundation”) of French cooking is stock, which requires meat, bones, and vegetables to be simmered gently to extract flavor (often after browning the ingredients by baking or frying). Stock can be reduced and then reduced again. Jean-Anthelme Brillat-Savarin wrote in the *Physiology of Taste*, appearing in 1825, that Bertrand, the steward of the Prince of Soubise, used fifty hams for one supper, but only one ham appeared on the table, the rest being essential for his *sauce espagnole*, white sauces, and so forth (1949, p. 54). The secret is the large quantity of gelatin produced when collagen in animal connective tissue is heated in water. Gelatin is a wonderful thickening agent owing to its peculiar, long molecular structure.

**Starch-thickened.** Starch in wheat and corn flours is useful because of its behavior in hot water. Put starch into cold water and the granules slowly sink, but hot water disrupts the long starch molecules so that the granules become amorphous networks of starch and water intermingled. A little flour can thicken a great deal of liquid. Eighteenth-century England was accused of having “sixty different religious sects, but only one sauce” (attributed to both Voltaire, 1694–1778, and Francesco Caraccioli, 1752–1799)—this was the ever-present “melted butter,” which was butter and (usually) water, thickened with flour.

**Emulsified.** Some sauces acquire their velvety consistency as emulsions, which are suspensions of one liquid in another with which it does not ordinarily mix, notably oil in water. The simplest is a dressing of oil and vinegar (dilute acetic acid) called *vinaigrette*. In *hollandaise*, *mayonnaise*, and their variations, the heated butter and oil are suspended with the help of egg yolk as an emulsifier.

**Preserved.** Vegetables and fruits are cooked and then immersed in vinegar and spices to make pickles and chutneys. Fish sauces are fermented, and soy sauce comes from fermenting soya beans. Bottled sauces have become important, too, notably tomato.

**Sweet.** Custards are sweet, moist, tender gels of egg protein. A creamy rather than solid custard is made by stirring continuously during heating to prevent the proteins from bonding into a solid mass. Sugar syrup is sugar dissolved in water with heating to arrive at the desired coloring.

### The French Triumph

One of the great French chefs of the twentieth century, Fernand Point, proclaimed the secret of his cuisine as follows: “Butter! Give me butter! Always more butter!” Much of it went into sauces, which, for him, were the mark of a good cook. Among the players in the kitchen, according to Point, “the saucier is a soloist.” He also wrote in *Ma Gastronomie* (1969) that the making of béarnaise sauce is a virtuoso performance: “What is it? An egg yolk, some shallots, some tarragon. . . . Well, believe me, it takes years of practice for a perfect result. Lift the eyes for a moment, and your sauce is unusable.”

Beginner, or even moderately experienced, cooks have difficulty not only preparing grand French sauces, but also differentiating the vast array of sauces, often with distinguished-sounding names, such as *périgueux*, *financière*, and *grandveneur*. Some chefs have attempted to identify the basic sauces (*saucés grandes* or *saucés mères*, meaning “great” or “mother” sauces), which, with various additions, become compound sauces (*saucés composées*). *Soubise* sauce has onions, Robert mustard, and *madeira*, the fortified wine of the same name. The “mother” sauces generate brown sauces (*saucés brunes*), derived from meat

stock, and white sauces (*sauces blanches*), derived from *béchamel* sauce (milk thickened with flour). Nonetheless, both stock and flour have thickened many sauces, and the browning of their original ingredients helps determine color, as when roux (equal quantities of butter and flour) is browned to a required extent. For a third family tree, hollandaise is the primary egg and butter sauce; béarnaise is its popular offspring. Then, there are cold sauces based on mayonnaise (yolks and oil).

An often-cited delineation of sauces is that of the renowned chef Auguste Escoffier, who wrote in his *Guide Culinaire* (1903), of five leading sauces: *espagnole* (brown stock, brown roux, and tomatoes), *velouté* (white stock, yellow roux), *béchamel* (milk, white roux), *tomate* (tomato), and *hollandaise* (butter, eggs, vinegar or lemon juice).

The nouvelle cuisine of the 1970s gave new life to sauces: by favoring “lighter” (less thick and flour-enriched) renditions, by rediscovering more rustic versions such as *beurre blanc* (butter, vinegar, shallots), and by featuring colorful purées, using one of the few important twentieth-century contributions to good cooking, the food processor. Though nouvelle chefs were also more likely to place the sauces underneath the food rather than on top of it, the goals remained the same. The first aim is a slightly sticky consistency that will coat other foods even when they are picked up with a fork. Thickening is achieved by the gelatin in stock, starch in the roux, reduction (evaporation), cream, egg emulsification, sugar syrup, and so on. The second aim is an intriguing flavor. Third, the sauce should look glossy, which usually means a long and careful clarification.

Jean-François Revel recounts in *Culture and Cuisine* (1982) that French chefs took flavor to a new level in the eighteenth century. They replaced “old-style cuisine of superimposition and mixture” (i.e., crude additions of flavors) with the “new cuisine of permeation and essences” (subtle combinations). He bases this view on the foreword to François Marin’s *Les Dons de Comus* [which means the Gifts of Comus, the Roman god of feasts], published in 1739. The author (thought to be two Jesuit priests) explained that the science of cooking was to mix and blend foods to make a harmonious whole, not dominated by any one ingredient.

English gastronomic writer Launcelot Sturgeon sought to relay his enthusiasm for the art that “binds the whole fabric of society” in two chapters, “On the Physical and Political Consequences of Sauces” and “On the Importance of Forming Good Connexions [Connections],” in his *Essays, Moral, Philosophical, and Stomachical*, originally published in 1822. He spoke of two primary indications of “the connexion [connection] of sauces,” namely, the harmony of the sauces and the social harmony they produced. Sauces, which are ingredients combined in “exquisite concord,” draw people together around a table, connecting them “by ties which no one ever wishes to dissolve.”

Modern chemistry took Sturgeon’s work one step further by showing how molecules tie sauces together. Culinary investigator Harold McGee details starch-thickening, emulsification, and other methods in *On Food and Cooking* (1984).

**SAUSAGE.** Essentially, sausages are just seasoned forcemeat. In cuisines around the world, however, countless variations have been played on this simple theme. Sausages were probably first invented as a means of preserving blood, offal, and small scraps of meat in convenient edible containers—the stomachs and intestines of the slaughtered animal. The earliest known reference to sausage dates to Greece in the eighth or ninth century B.C.E. It appears in Homer’s *Odyssey* (XX: 24-27), where Odysseus, lying in his bed, is seen

rolling from side to side  
as a cook turns a sausage, big with blood  
and fat, at a scorching blaze, without a pause,  
to broil it quick

They are also found in Apicius’s *De re coquinaria* (Rome, first century C.E.), a cookbook that was clearly intended for diners with discriminating palates. While sausages may have begun in frugality, they had already evolved into delicacies worthy of a gourmet’s attentions.

Sausage stuffer. Berks County, Pennsylvania, circa 1860. Wood handle, tin and copper. Ground meat was pressed through the tube into a gut, which was then twisted to make sausages. ROUGH-WOOD COLLECTION. PHOTO CHEW & COMPANY.

In form, sausages may be patties of freshly chopped and seasoned meat or they may be stuffed in casings, dried, fermented, smoked, or produced using any combination of these techniques. The meats can be ground exceedingly fine (*weisswurst*) or simply cut into large chunks (headcheese). Some are eaten cooked, using any of the traditional methods for cooking meats, while some are so heavily cured and smoked that they can safely be eaten raw (*salame crudo*).

Pork is the meat most commonly used to produce sausages, although almost any sort of protein will do (sausages have even been made from gluten and soy proteins) providing they contain enough fat to maintain a juicy product. Beef, chicken, duck, lamb, seafood, and veal have all been used in sausages. Game, such as venison or rabbit, tends to be very lean, so pork fat or beef suet are usually added. Typically, a sausage forcemeat contains 20 to 30 percent—and sometimes as much as 50 percent—fat by weight. Fats chosen must be flavorful and not too soft, so that they don't melt out too quickly during cooking. Depending on cooking method, much of the fat may be removed before the sausage comes to the table.

All sausages contain salt (indeed, the word “sausage” is descended from the Latin *salsus*, meaning ‘salted’). Salt serves three purposes. It acts to preserve perishable meats, killing some bacteria through osmotic pressure. In addition, salt dissolves some globular protein from the meats, which then acts as a binding matrix for the bits of meat when the sausage is cooked. The globular protein is released when the meats are ground or kneaded (the

sausagemaker can see when this has occurred because the forcemeat becomes sticky). Salt, of course, also provides flavor, and it reinforces the flavors of other seasonings, especially in foods that are served cold.

Seasonings vary according to the cuisine producing the sausage. Black pepper is almost universal; in fact, the simplest fresh Italian sausages contain nothing but pork, salt, and pepper (Italian sausages made in the United States almost always add fennel seeds and red pepper). Garlic is a key ingredient in sausages of many countries, including Germany, Hungary, France, Poland, Portugal, Spain, and the United States. Chili pepper, in forms ranging from dried flakes to cayenne to paprika, appears in sausages around the world (although its use in sausages is limited in northern cuisines that typically avoid hot pepper). Fresh breakfast-type sausages usually contain sage, and often marjoram. Cloves, cinnamon, and nutmeg are sometimes used, especially in black (blood) sausages. Chinese sweet sausages (*lop cheong*) are flavored with sugar, soy sauce and five spice powder (a mixture usually consisting of ground cassia, cloves, fennel seeds, star anise, and Szechuan pepper).

Natural casings include sheep casings (breakfast links, chipolata), hog casings (Italian sausage, bratwurst), hog bungs (liverwurst), caul fat (*crêpinettes*), beef middles (salami), and beef rounds (mortadella). Haggis, the Scottish national dish, is nothing more than a large sausage made of seasoned sheep organ meats and oats, stuffed in the sheep's stomach. Synthetic casings, made of cellulose, collagen, or plastic, can be made in any size, and are used

for spreadable pâtélike preparations (braunschweiger), salamis and other cold cuts, and skinless frankfurters. Dolmas, grape leaves stuffed with a mixture of seasoned lamb and rice, can even be considered a form of sausage.

Sausages are often dried by hanging, in cool circulating air, to preserve them as well as enhance their flavor and texture. Once they are fully dried, they can be kept unrefrigerated for weeks. Before they are dry, however, they can spoil, so a curing salt—such as Prague powder, a mixture of salt and sodium nitrite—is used to prevent the development of the bacteria (*Clostridium botulinum*) that cause botulism. The nitrite has an additional advantage; it prevents the cooked meat from turning gray (the characteristic pink color of cured hams results from the nitrite in the cure). Nitrites, used in recommended quantities, do not cause the development of carcinogenic nitrosamines that were formerly found in cooked meats containing nitrates (saltpeter). Some dried sausages are also fermented, either with naturally occurring organisms or through the addition of a starter (lactobacillus) to the forcemeat. These bacteria produce lactic acid, which preserves the meat while providing a tangy flavor. *Sopressata* and some kinds of chorizo are fermented, but quick recipes for fresh chorizo substitute a little vinegar for the lactic acid that would have developed through fermentation.

Smoking adds flavor to sausages. It acts as a preservative, both by adding a number of phenolic compounds found in smoke, and by forming a tough coating on the outside of the sausage. This impervious layer is known as the pellicle.

Sausages continue to appear in recipes around the world, even after the development of other means of preserving meats. In many peasant cultures, the largely vegetarian diet is enhanced by small quantities of sausage. In modern diets sausages make up for their high fat and

sodium content by contributing more flavor and variety than their size would suggest. Thus sausages satisfy sophisticated palates with lower quantities of food.

**SCANDINAVIA.** See **Nordic Countries.**

**SCHOOL MEALS.** Operating primarily in industrialized countries, such as England, Japan, and the United States, school meals programs have become an integral part of the school day. If efforts by the United Nations and the United States are successful, up to 20 million children in developing countries will be able to participate in a similar program for the first time beginning in the early years of the twenty-first century.

Typically started on a local level, school feeding programs emerged as recognition grew of the link between malnourishment and academic performance. Numerous cities in Europe and the United States, including London, Milan, New York, Paris, and Zurich, established feeding programs by the early twentieth century. Over time, the local programs evolved into statewide and nationwide programs. In 1946 the United States established its National School Lunch Program (NSLP), after finding that many men were rejected for military service during World War II due to malnutri-

tion. The lunch program has grown from serving daily 4.6 million children in 1947 to more than 26 million by the end of the twentieth century. In the 1960s the feeding program was expanded to include a school breakfast program and a summer feeding program primarily targeted to low-income children. In the United States school meals programs are required to offer free and reduced-price meals to children from low-income families. About half of the children participating in the NSLP receive free lunches.

Until 1996, U.S. school meals were required to comply with a meal pattern designed to meet, on average, one-third or one-fourth of the U.S. Recommended Dietary Allowances (RDA) for essential nutrients for the lunch or breakfast programs, respectively. The meal pattern for lunch consisted of one serving of meat or meat alternate, two or more servings of vegetables or fruits, a serving of bread or bread alternate, and a serving of fluid milk. Until 1974 lunches were also required to include a teaspoon of butter. Children's diets were found to be high in calories, fat, cholesterol, and sodium, and the number of children who were overweight had more than doubled between 1960 and 1990. In 1995 the United States Department of Agriculture updated its nutritional standards to reflect current scientific knowledge about disease prevention and health promotion. For instance, it is now standard to require that school meals contain no more than 30 percent calories from fat and 10 percent from saturated fat. Earlier in the decade a nationwide study of school meals had found that school lunch and breakfast programs met the RDA requirements, but were well above the nutritional guidelines for fat, saturated fat, cholesterol, and sodium. As a result, both school lunch and breakfast programs, for the first time, had to conform to the 1990 Dietary Guidelines for Americans. States are responsible for ensuring that schools are compliant. Since then most of the nation's 96,000 schools have substantially reduced their fat and saturated fat levels, and increased their levels of carbohydrates.

At times, the dual mission of providing nutritious school meals and encouraging the consumption of domestically grown commodities has created a tension between nutrition advocates and farm groups. The distribution of government commodities was often viewed by the nutrition and health communities as a barrier to providing healthy meals. This conflict has diminished with the new nutrition standards and policy changes in commodity purchases that include increased purchases of fresh produce and lower fat items. Unresolved issues seen by nutrition advocates include the presence of junk food vending machines in schools and the growing number of private food service companies replacing or competing with the government's school meals programs.

**SCURVY.** A corruption of the earlier word "scorby," scurvy is the name given to the disease that is the consequence of a prolonged deprivation of vitamin C. The minimum daily requirement to prevent the disease is approximately 7 mg, but it takes several weeks of depletion of body reserves before the problem becomes evident. There are many descriptions of the disease as it appeared among sailors engaged in the long voyages that began to be undertaken from the end of the fifteenth century. After ten or more weeks at sea, men began to experience general pain and stiffness, while their lower body became covered with large purple spots. In addition their gums would swell and grow over their teeth, which became loose; and old wounds would reopen. Finally, sufferers would die suddenly, "in the middle of a sentence," to the astonishment of their mates. This is now explained as the consequence of impaired protein synthesis, with connective tissues weakening, so that the wall of a major artery would finally burst. It soon was discovered that the disease could be prevented, and even cured, by sailors consuming fresh fruit and vegetables. Long sea voyages were only indirectly responsible, by preventing crews from living on anything but foods that could be stored for long periods, like salt meat, dried peas, and flour that could be cooked into bread and puddings. The same disease appeared on land when fresh food was unavailable for long periods, as in the California gold rush, for example. The first "antiscorbutic" (i.e., antiscorvy) foods to be prized by sailors were oranges and lemons, but they would become moldy on long voyages, and juices preserved with brandy or rum were more stable alternatives that also proved to be more palatable. Sailors in the British navy were required, from early in the nineteenth century, to take a portion of lime juice in their daily ration of rum; men from other navies called them "limeys" as a term of abuse, implying that "real men" did not need to drink fruit juice. Another tradition among sailors on long whaling expeditions was to take a large store of potatoes. These are not very rich in the vitamin but contain enough to prevent the disease if one is eaten freshly cooked every day.

In the early twenty-first century the disease still appears occasionally in adults, typically as "widowers' scurvy," among men who have never learned to cook and,

when left to fend for themselves, subsist on things like breakfast cereals and sandwiches made from bread and cheese or ham. It also has appeared in people living on very restricted “fad” diets, such as a Zen macrobiotic diet of brown rice sprinkled with sesame seeds.

With the recognition of the importance of bacteria in causing diseases, at the end of the nineteenth century, it became a practice in some cities to sterilize cows’ milk by autoclaving it. Children’s deaths from “summer diarrhea” were reduced greatly as a result of this practice. However, this processing also resulted in the destruction of most of the vitamin C in the milk and, when it was fed to infants with only a cereal supplement, scurvy became a common problem. The addition of orange juice to the infants’ diets provided a simple solution. With modern technology, milk can be freed from pathogens and potatoes can be dried under milder conditions, so that vitamin C is preserved; alternatively, the synthetic vitamin can be added to restore vitamin C levels in foods.

**SEABIRDS AND THEIR EGGS.** Seabirds and their eggs played an important part in the coastal economies and life patterns of many areas of the North Atlantic fringes of Europe into the twentieth century. In the struggle for survival in peripheral socioeconomic settings, the harvesting of seabirds and their eggs was a means of providing seasonal fresh foods and of augmenting the supply of preserved foodstuffs for winter and spring. The exploitation of these natural resources was an activity that required adaptation to the environment, ingenuity, courage, and a taste for foodstuffs often considered unpalatable by inland dwellers.

Seabird fowling and egg collection were undertaken by men while women were normally involved in the preparation and processing of the birds and eggs for household food or sale. Since seabirds exist primarily on the sea but come to rocks, cliffs or grassy sea-slopes, to breed and roost, they and their eggs were normally taken from these habitats by scaling up or down the rocks, cliffs or slopes. Bird-catching was a complex activity and a wide range of catching methods were employed depending on the roosting habits of the birds. Among the most common along the North Atlantic region were catching or seizing by hand, using snares consisting of a single noose or jaw attached to the end of a fowling rod, arranging multiple nooses on the ground, and using nets of various kinds, to trap the birds.

Seabird fowling and egg collecting varied in intensity along the north Atlantic region from Iceland in the north to Ireland in the south. The harvesting of seabirds on the Faroe Islands was described by Kenneth Williamson in 1948 and more recently by Arne Nørrevang (1977). John R. Baldwin has compared the fowling equipment, techniques and allied terminology of the Faroes with the centuries-old practice of seabird fowling on islands off the northwestern and northern coasts of Scotland, an activity that has attracted attention for several centuries. Sir Donald Munro mentions Sula Sgeir in that context in 1549, and Martin Martin in *A Description of the Western Islands of Scotland* (c. 1695), tells that the inhabitants of the isle of St. Kilda (abandoned since 1930) killed and preserved an enormous quantity of seabirds and preserved seabirds’ eggs in peat ash, which gave then an astringent taste. St. Kilda was, in fact, unique in Scotland for its organized farming of the fowling cliffs. The year’s cycle has been described as “killing of gannets and some shearwaters in April, collecting eggs of puffins and catching fulmars in May, snaring puffins in July, catching fulmars and

Finlay MacQueen snaring puffins on the isle of St. Kilda, west of the Outer Hebrides, Scotland. COURTESY OF R. L. ATKINSON, SCHOOL OF SCOTTISH STUDIES PHOTOGRAPHIC COLLECTION, EDINBURGH.

gannets in August and catching young gannets in September” (Fenton, 1987, p. 170).

These activities on St. Kilda were a response to an extreme environment. Elsewhere in Scotland wild birds and their eggs were welcome seasonal supplements to the diet, rather than being a major focus of economic activity. May was the time for harvesting the eggs of gulls, fulmars, puffins, razor-bills, guillemots and so on. Guillemot and gannet flesh was eaten. A limited cull of the young of the gannet (Gaelic: *guga*) still takes place on Suileisgeir (Gaelic: *Sula Sgeir*, “gannet reef”), a small barren island with craggy cliffs covered in guano, lying forty miles northwest of Lewis. This centuries-old tradition is carried on by the community of Ness, at the northernmost tip of the Island of Lewis, also in the Outer Hebrides. It is the only surviving gannet hunt in the British Isles.

Gannet hunting on Suileisgeir was regulated by the First Bird Protection Act of 1869, which gave the men of Ness a special dispensation to take gannet chicks. Nowadays, annual licences to take 2,000 such birds, starting only from the first week in September, when the birds are about three months old, are necessary. A crew of ten men spend two weeks on the rock catching and prepar-

ing the birds. All equipment, food supplies, including fresh water, and salt to dress the birds, must be ferried to the rock.

The method of catching has changed little over the centuries, and men still go down the steep cliff-faces on ropes to trap the birds. They are caught using a long fowling rod with an iron jaw fixed at the end, which is put around the bird’s neck and pulled closed by a rope to trap the bird. The manner of processing has also changed little over time. They are plucked, and the down is removed by singeing over a peat flame, which apparently confers its unique flavor on the flesh. The ribcage and entrails are removed, and cuts made in the four pockets of meat at the wings and legs are packed with salt. The finished birds are then carefully laid in a wheel-like formation, lair upon lair, in order to retain the pickle drawn from the flesh by the salt so that it will not become hard and salty.

The birds are sold on the quay on return and are much in demand. They are scrubbed clean with washing soda, placed in a pot, covered with boiling water and boiled for twenty minutes. The water is then changed and the bird is boiled for a further twenty minutes. This procedure is repeated a third time. In this way the salt

content in the bird is reduced. The flesh has the texture of meat with a salty and fishy flavour. It is, indeed, an acquired taste.

The role of the gannet chick as a food in the Ness community has changed greatly in the course of the twentieth century. No longer necessary as a welcome variation in diet, it has become somewhat of a delicacy which embodies a sense of identity for the people of Ness.

Seabird fowling and egg collecting were also seasonal activities along parts of the Atlantic coast of Ireland, from Rathlin island in the northeast where the cliffs and sea-slopes were apportioned in strips, and individual men in search of eggs and birds would lower themselves on ropes attached to iron spikes in the cliff edge, westwards to the great cliffs in southwest Donegal, northwest county Mayo, around the Conamara coast, in the Aran Islands in Galway Bay, and in county Clare on the towering Cliffs of Moher, in some cases into the twentieth century.

Further south on the islands and coastlands of county Kerry, seabirds, their eggs and feathers, were important in the food-provision strategies and local market economy of the Blasket Islands and contiguous mainland from at least the eighteenth century. The most westerly of the Blasket Island group, a towering rock appropriately named Tiarach “westerly isle” was the seabirds’ haunt par excellence especially of the puffin population, whose eggs and chicks were exploited for food.

On the Great Blasket Island the eggs of the oyster catcher, guillemot, razor-bill, puffin and seagull were eaten. The flesh of guillemot, razor-bill and to some extent that of the Manx shearwater, cormorant and storm petrel were eaten, fresh, or preserved by salting for later use. Salted seabird were also sold on the mainland. The young of the puffin was considered the “chicken of the sea” and was much sought after. Because of its fat content it was roasted in a pot or grilled on a tongs laid over live cinders to allow some of the fat to escape. The storm petrel, a very small bird, was similarly cooked to discharge its fat. Regarded as a delicacy, and an acquired taste, it appears to have been swallowed whole rather than chewed.

By the early twentieth century seabird-fowling was no longer an organized, specific food-provision strategy on the Great Blasket Island due in some measure to the expansion and demands of the fishing industry during the summer months, but also to changing tastes, reflected, too, in the cessation of the hunting of seals for food.

Gannet hunting, for the flesh and feathers of the young chicks, was still practiced commercially on the Little Skellig, a great towering sea-crag lying in the Atlantic to the south of the Blasket Islands, and the second largest gannetry worldwide, in the course of the nineteenth century. By the end of that century, however, this activity was no longer viable, and the rock was too distant and the sea too rough for local light rowing-craft to reach. And the very strong and fishy taste of these birds was no longer desired.

**SEEDS, STORAGE OF.** Seeds are by far the single most essential cultivated source of food, with wheat, rice, corn, soybean, barley, millet, and sorghum providing the vast majority of food for humans and their domesticated animals. While root and tuber crops, such as potatoes, yams, sweet potatoes, and cassava, are important sources of food in certain regions, they come in a distant second behind seeds. Besides serving as food, seeds also give rise to the next generation of crops. In general, annual crops are grown from seed (for example, grains, legumes, and vegetables), while perennial crops rely on vegetative propagation. Seeds are therefore stored not only to ensure a stable source of food, but also to provide the propagules from which additional crops can be grown.

## Importance of Seeds

Modern agriculture is based on the establishment and growth of uniform stands of crops. Plant density should be uniform throughout a field, as should the plant age and stage of development. Uniform propagules and growing conditions are necessary to assure crop uniformity. Propagules are either produced sexually (as in seeds), or asexually (through cutting, grafting, budding, and division, etc.). Even vegetatively produced crops (such as tree fruits) use seed to produce rootstocks and in breeding programs. Seeds are composed of an embryo, stored food, and a protective covering. They fulfill a number of functions besides being the product of sexual reproduction. Seeds assist in the replication of individuals in a population, aid in dispersal of the species into new areas, and provide protection for the delicate embryo. The food sequestered in the seed to nourish the germinating embryo and growing seedling is the source of our food, while the embryo is the source of a new plant.

## Seeds Stored for Food

By far the greatest bulk of stored seeds are used as food. Huge silos store wheat, corn, rice, soybeans, and other grain, and legume crops prior to their being processed into flour, bread, corn meal, cornstarch, and the myriad other products we consume daily. Seed-derived vegetable protein can be mixed with colors and flavors and then extruded under moist heat and high pressure to produce various shaped and sized products that can be used in place of meat. Oils can be extracted from seeds, and sweeteners can be produced from the starch in seeds through enzyme digestion. Storage conditions for these seeds are designed to minimize loss of food value resulting from seed respiration and metabolism, and contamination or loss due to the growth of mold and insects, while at the same time retaining desired processing qualities. Low degrees of moisture and temperature are the two most important factors in storage of seeds for food. Both of these factors reduce seed respiration and the growth of pests.

## Seeds Stored for Propagation

If seeds are not stored in a manner that maintains their vigor and viability, there will be no food for the next season. Seed vigor and viability is primarily based on generic factors, so differences occur among species, and in varieties within a species. The conditions under which seeds were produced can also affect seed longevity. Temperature, rainfall, humidity, nutrition, and diseases during seed production all influence seed viability, as does seed maturity when harvested. Mature seeds remain viable longer than immature seeds. Seed vigor usually decreases with time in storage; exceptions are seeds in which the embryo must develop or mature before they are ready to germinate (as with elm).

There are three general categories of seeds based on their desiccation tolerance and the time they remain vi-

able in storage. Most annual and biennial crops, and horticultural crops produce orthodox, or desiccant-tolerant, seeds that can easily be stored for many years in a dry, cool storage environment. These crops include grains, legumes, vegetables, floral crops, and temperate fruit trees. By contrast, recalcitrant, or desiccant-intolerant, seeds are difficult to store and usually remain viable for only a few weeks or months before they are killed by desiccation. Desiccant-intolerant seeds do not enter dormancy after maturing. Their continued respiration and physiological activity leads to rapid deterioration. They must be planted while still fresh, or stored moist at low temperatures. Even if properly stored, they can only be kept for short periods of time before they succumb to fungal or bacterial rots, or exhaust their food reserves. They include tropical perennials (such as avocado, mango, and coconut) and some temperate deciduous trees (such as chestnut, buckeye, maple, and oak). Between these two extremes are the intermediate seeds that can be stored for a few years if maintained under proper conditions of temperature and humidity. They include tropical and subtropical perennials (for example, coffee, citrus, macadamia, and papaya), and some tree nuts (such as hazelnut, hickory, pecan, and walnut).

In order to maintain seed quality in storage, the relative humidity of the air (in percentage relative humidity, or RH) and the temperature of the seeds (in degrees Fahrenheit) should total, as a general rule, less than 100. This means that the relative humidity around seeds stored at room temperature (about 72°F) should be less than 28 percent, while it should be less than 63 percent for seeds stored in a household refrigerator (about 37°F). Storage life of orthodox seeds is doubled for every 10°F drop in temperature, or every 1 percent drop in seed moisture content. Seeds are hygroscopic, meaning they will absorb or lose water from the atmosphere until they come into equilibrium. At the same relative humidity, seeds containing mainly carbohydrates will contain more water than do oil-containing seeds. At a relative humidity of between 20 and 70 percent, the seed-moisture content of a carbohydrate containing wheat seeds is around 30 percent more than that of oil-containing soybean seeds at the same relative humidity. So the relative humidity around stored seeds must be adjusted to produce the same level of moisture in seeds of different composition.

Whether plants were selected for domestication because they produced seeds that stored well, or whether plants were bred to produce seeds that stored well as they were domesticated, the seeds of most cultivated plants are orthodox and can be stored for a few years at near ambient conditions of moisture and temperature. The vigor and viability of most seeds of cultivated annuals can be maintained for two to five years under favorable storage conditions of 30 to 60 percent RH (8 to 14 percent seed-moisture content) and 40 to 60°F. Difficult-to-store seeds can be kept for extended periods at very low temperatures. This technique of cryopreservation can maintain

Seed storage warehouse of Philadelphia seedsman Robert Buist. From an 1891 wholesale seed catalog, ROUGHWOOD COLLECTION.

recalcitrant seed for decades at liquid nitrogen temperatures ( $-320^{\circ}\text{F}$ ;  $-196^{\circ}\text{C}$ ). However, the vigor of seeds stored at even these low temperatures declines over time. The continued maintenance of specific seed lines requires that they periodically be removed from storage and used to produce a new crop of seeds. Seed storage facilities, therefore, need not only modern storage equipment, but also the land, personnel, and expertise to periodically grow the stored seeds under conditions that maintain their genetic purity.

High vigor is characterized by the seed's ability to germinate and for the embryo to grow under stressful conditions that can include compacted soil, pathogens, salinity, and cold or hot temperatures. Seeds with higher vigor possess greater storage potential and can be stored for longer periods before the seed becomes nonviable. Both vigor and viability decline gradually during the early stages of seed storage; they parallel one another initially, with vigor ultimately declining in advance of viability. Later in storage, there is a sharp decline in both, until the seed only produces a weak seedling that quickly succumbs to environmental or pathogenic stresses.

Seeds that are planted in a field should have been sorted to produce a group of seeds that will germinate and grow at the same rate to produce uniform plants. Cracked, deformed, and small seeds should be eliminated in this winnowing process. In addition to selecting robust seeds, various preplanting treatments can increase

seed viability and ensure uniform seedling establishment. Seeds' viability can be increased by partially germinating them under optimal conditions before planting. Holding seeds in an aerated aqueous solution for a week or so and then immediately planting them or drying and planting them later can also increase viability. The osmotic strength of the solution allows the seeds to take up water but not to germinate. Another method is to enclose each seed in a porous clay coating that contains fertilizers or fungicides to assist the seedling during early stages of growth.

### Preparation of Seeds for Storage

Seeds should be harvested after maturing on the plant, separated from the fruit or protective plant parts in which they developed, and cleaned. Desiccant-tolerant seeds can be slowly air dried over a few days at low relative humidity and then sealed in moisture-tight containers before being placed in a refrigerator. If the seeds are sufficiently dry, they can be stored in the freezer section. Desiccant-intolerant seeds must be stored moist and need to be planted as soon as possible.

### Stored Seeds Preserve Genetic Resources

Before the advent of scientific plant breeding, farmers would keep seed from the previous harvest to plant for the next season. From this process, numerous land races of the major crops developed that were specifically

adapted to the conditions of their environment, such as climate, cultural practices, diseases, pests, soils, weeds. The availability of commercially produced seed with improved quality characteristics, pest resistance, and yields have supplanted many of these local varieties, and many have disappeared. Older crop and heirloom varieties of many horticultural and ornamental plants have also been lost because no one kept their seeds. Recognizing that such seeds may contain traits and genes (for example, pest resistance) whose introduction could improve modern varieties, private and governmental groups have developed seed banks and germplasm repositories to collect and preserve seeds and other propagules for long periods of time. These facilities include the National Seed Storage Laboratory in Fort Collins, Colorado; the Seed Savers Exchange in Decorah, Iowa; and the National Genetic Resources Program (NGRP), authorized in 1990 by the U.S. Congress. The Plant Sciences Institute (PSI), part of the National Germplasm Resources Laboratory (NGRL), is located at the Beltsville Agricultural Research Center, Agricultural Research Service, U.S. Department of Agriculture.

**SENSATION AND THE SENSES.** Striving for variety and intensity in sensory experiences may be a fundamental human characteristic, likely reflecting our evolutionary history as both foragers of foods and omnivores. The enduring popularity of high-speed activities such as roller coaster rides or extreme sports, as well as films or computer games with impressive visual and sound effects, points to sensation seeking as still being an important aspect of many people's lives. Yet, in terms of the *range* of sensations they evoke, these experiences might be con-

sidered trivial by comparison with those delivered every day by foods and beverages. Particularly in the chemical senses (the collective term for smell, taste, and pungency), food consumption provides a continuous stream of sensory information to be processed and evaluated. Far from being mundane, even eating an apple provides an enormously varied set of sensations that begins even prior to the first bite.

#### Appearances and Expectations

When it comes to assigning priority to sensory information, humans are visual animals. Given uncertainty or conflict in the sensory information we receive, we tend to rely most on what we see. This is the basis of ventriloquism illusions. It is perhaps surprising, though, that a visual bias is so important with foods, where we might think that odors and tastes should predominate. Nevertheless, initial judgments of foods and beverages very often rely on appearances. In fact, our ability to identify even common flavors is typically very poor, so vision may sometimes be a more reliable source of information. Thus, foods that are miscolored—for example, a lime drink colored red—are often identified on the basis of the color rather than the flavor.

As well as being appreciated in their own right, visual aspects of foods provide important clues as to other sensory qualities, creating expectations about what we are soon to consume. We learn to associate the appearance of a food with its other sensory qualities, and the impact of these associations is perhaps most obvious in the effects of food colors. Whether an apple is red or green, for example, will lead us to expect a certain degree of ripeness and, often, quite specific levels of sweetness and acidity. Surface textures and color brightness can also provide clues to internal textural properties such as hardness. Because of such associations, colors can also influence *what* we perceive. Adding red coloring to a sweet solution increases the perceived sweetness, while the addition of any color to a solution containing an odor increases how intense we perceive that odor to be.

Expectations about a food's sensory properties can also be created in advance of consumption by information about a food, for example, on labels. These have the ability to influence a product's acceptability. Serious mismatches between what we expect a product to taste like and its actual sensory properties can be an important determinant of whether the food is ever consumed again. Like color, information can also be powerful enough to influence perceptions. For instance, labeling a product as high in fat has been shown to lead to higher ratings of "fattiness" and lower ratings of flavor intensity, relative to the same product with a low-fat label. The mechanism appears to be that, when mismatches between prior expectations and the reality of the product are relatively minor, "assimilation" takes place. That is, perceptions and preferences can be "brought into line" with product claims. These effects are an excellent reminder that, ul-

timately, perception is a cognitive process that receives information both from the sensory impact of food ingredients and from other sources of information about the food.

### Odor Perception

While the odor of a food can also generate expectations for other sensory properties, its most valuable role is to help us to identify foods. Olfaction provides us with more information about what we consume than perhaps any other sense. Most important, whether as part of a flavor in the mouth or as an aroma that we sniff, odors reliably inform us whether we have experienced a food before. To a great extent, this assists us in making a decision to consume or not.

Olfaction has been called a dual sense. Both at a distance from the food, and when the food is in the mouth, our sense of smell acts as a detector of volatile (i.e., gaseous) chemical compounds. The mixture of compounds that we perceive as apple odor reach the olfactory receptors in the patch of tissue known as the olfactory epithelium, a mucus membrane at the top and back of the complex maze of passages found within the nose. The physiological processes that such odors initiate in the receptors are not completely understood. We do know, however, that the small odor molecules bind to receptor proteins present on the cilia, hair-like extensions of olfactory nerve cells that protrude from the epithelium. This binding initiates complex sequences of biochemical changes leading to depolarization, and firing, of the olfactory cell. This electrical signal travels via the olfactory nerve to the olfactory bulb in the brain.

How we recognize such neural signals as specific odors is perhaps *the* crucial question in the science of olfaction, particularly if we consider just how many odorants humans are capable of detecting. In stark contrast to the relatively small number of different taste qualities (see below), we can certainly perceive thousands, if not tens of thousands, of distinct odor qualities. Moreover, there does not seem to be any underlying organizing principle that we can use to classify these qualities. Historically, various schemes have been proposed for categorizing odors. Linnaeus, for example, classified odors as “aromatic,” “fragrant,” “musky,” “garlicky,” “goaty,” “repulsive,” and “nauseating.” This and many other classification systems suffer from the use of categories that are either too general (“fragrant”) or clearly related to the acceptability of the odor, rather than its sensory properties (“repulsive,” “nauseating”).

In practice, odors are often classified into categories that make sense to their users, whether they are wine-makers, flavorists, or perfumers, as well as having practical applications. While they often have an internal logic and consistency—fruit odors may be grouped together, for instance—such classifications relate primarily to the object producing the odor, to a lesser extent to the odor

chemistry, and not at all to how the brain codes the odor information. The molecular properties of the odorant must be responsible a priori for odor quality, but any laws that could allow us to reliably predict a particular quality from those properties are not as yet apparent. Instances of dissociations between structure and quality make this a challenging task. The compounds D-carvone and L-carvone have the same structure, differing only in that they are optical isomers (effectively, molecular mirror images) of one another, yet one smells of spearmint and the other of caraway.

A milestone in our understanding of the mechanism of odor perception came in 1991, when Linda Buck and Richard Axel of Columbia University identified a family of genes that encode olfactory receptor proteins. It is thought that this family, now believed to include more than 1,000 genes or around 3 percent of our total genome, is able to generate an equally large number of receptors. It is unlikely, though, that we have a unique receptor for each odorant since this would seem to be an inefficient way of coding. The most promising hypothesis regarding olfactory coding suggests that patterns of activity across different receptors, perhaps each expressed by a different member of the gene family, form the basis of odor qualities. Olfactory coding is thought to be also partly mediated by organization of the olfactory epithelium into four different zones, each zone containing receptors expressed by different genes. A given odor will likely activate receptors in more than one zone, creating a spatial, as well as a receptor-specific, code.

Any complete theory of odor perception must explain how what we perceive as apple odor is the product not just of a single apple-like compound, but of the mixture of the compounds 2-methylbutyl acetate, butanol, and hexyl acetate (amongst many others), none of which smells uniquely of apple. The odors of the majority of the foods and beverages that we consume consist of mixtures of the odors of many separate compounds. For example, hundreds of different compounds, each with their own distinct odor, combine to make coffee and chocolate odors. What we perceive, though, is a single unique quality. A major question in our attempts to understand how the brain processes odors is how this information is combined. There does seem to be some sort of limit to the number of individual odors that we can combine and still detect. Beyond a mixture of three or four different odor qualities, we are unable to say which of a set of individual odors the mixture contains, even if we are very familiar with those components. At the same time, however (and seemingly paradoxically), complex odors can contain “notes” in addition to having an overall quality, although these notes cannot be related to the odors of the specific chemical compounds in the mixture. One of the challenges for food scientists in industry is to be able to identify which of the multitude of chemical compounds within a food are essential for producing its characteristic odor and flavor.

## HOW MANY TASTES?

The conventional wisdom in both the scientific community and among the general public is that taste is composed of a set of discrete qualities, almost like separate senses. Sweet, sour, salty, and bitter have formed the core of our understanding of taste since Aristotle. While other tastes have been proposed from time to time—astrigent, pungent, fatty, insipid, alkaline, to name some—these four qualities have almost always been recognized as fundamental.

Outside of the laboratory, however, we seldom experience so-called pure tastes. Fruits are often simultaneously sweet, bitter, and sour, and savory dishes may be salty, sweet, sour, and high in *umami*. Similarly, many chemicals that produce tastes are not “pure” examples. Potassium chloride is both bitter and salty. To what extent do we perceive these mixtures as sets of basic qualities, and to what extent as unique tastes themselves? Are such compounds steps along a continuum of tastes (as orange exists along a continuum of colors from yellow to red), rather than having discrete and separate qualities? These questions challenge the orthodoxy of a set of discrete basic tastes.

The recent evidence that the taste of glutamate appears to constitute a fifth basic taste, *umami*, is somewhat embarrassing for those who strongly argued for four primary qualities. If five, then why not six, or seven? In fact, there is evidence to support the notion of a taste associated with fatty acids and of the quality metallic as an independent taste. A case can be made for the survival value of such tastes: fats are important sources of energy, while the salts of metals such as iron, copper, and zinc are both metabolically necessary and toxic at high levels. Arguments have also been mounted for recognition of the tastes of other amino acids and starch as basic qualities.

Beyond such challenges to the concept of four (five) basic tastes, it has been argued that the whole notion of basic tastes is flawed. Robert Erickson and Susan Schiffman, both of Duke University, have proposed that the paradigm of a limited number of basic tastes has impeded our understanding of this sensory system. In the early part of the twentieth century, Hans Henning proposed that the four basic tastes could be represented at the points of a tetrahedron. Did Henning mean to convey that there were no intervening qualities on the tetrahedron’s surface or were the basic tastes merely distinct points on

continua? This influential attempt to classify tastes has been interpreted both ways, but Erickson and Schiffman argue that the evidence favors the latter interpretation. They point out that there are no strong physiological reasons to accept only four basic tastes. There appear to be more than four transduction (receptor) mechanisms for taste; not only are there not four distinct types of taste neurons in the brain, but taste cells are broadly sensitive to many qualities.

### *What do we really perceive?*

Erickson and Schiffman have suggested that the acceptance of the idea of a limited number of basic qualities prejudices our understanding of taste. In other words, if you accept that sweet, sour, salty, and bitter are the only tastes we can detect, then all taste sensations will be *a priori* classified into one of these categories. In one study, they asked subjects to indicate which of a variety of taste compounds, some of them mixtures of basic tastes, were singular tastes or mixtures of tastes. Many of the mixtures were viewed as a single taste, sometimes one that was distinct from the four basic tastes. Spatial mapping of the quality of a selection of tastants, based on ratings of the similarity of each pair (more similar tastants are mapped closer together, and so on), also did not conform to a pattern that could be represented by four basic qualities.

Similarly, Michael O’Mahony and colleagues at the University of California, Davis, asked subjects to sort a number of tastants into groups based on taste quality, but without using the traditional category names. Their subjects not only came up with more than four categories, but also used more than four self-generated labels to describe the different qualities. When asked to use only the four traditional qualities, these subjects were forced to label different groups using the same word, suggesting that restricting labels to the four terms was inadequate to describe the range of taste experiences.

Despite all these potential problems with the doctrine of basic tastes, there is widespread acceptance of sweet, sour, salty, bitter and, increasingly, *umami* as fundamental taste qualities, although perhaps not the only qualities. Certainly, for the foreseeable future, the existence of distinct, basic tastes will continue to be the key assumption behind research aimed at elucidating the fundamental mechanisms of taste perception.

## Flavor: Sensory Qualities in the Mouth

It is only after we have taken a bite that the characteristic apple flavor, consisting of odors and tastes, emerges. After entering the mouth, the same odor compounds that

we detected previously, now released and concentrated by the combined actions of heating and chewing, reach the olfactory receptors via the nasopharyngeal passage at the back of the mouth, a process known as retronasal percep-

tion. The reason we commonly refer to characteristic food qualities as tastes—apple taste, coffee taste, and so on—is that we are not conscious of this alternate route for the sense of smell. In fact, these “tastes” are mainly odors.

Odor and taste perceptions are so well integrated in flavors that there are seldom any obvious signs as to where one sense ends and the other begins. This gives rise to the illusion that retronasal olfactory qualities are perceived in the mouth. Our language both reflects and encourages this confusion, in that we use the terms “taste” and “flavor” interchangeably. Simply holding the nose while a food or drink is in the mouth is sufficient, however, to demonstrate just how large a contribution the sense of smell makes to flavor. The complaint of loss of taste during a head cold is also a consequence of this misunderstanding. In fact, taste is largely unaffected, and it is the sense of smell that suffers.

At the same time as the odor volatiles in our apple are released during chewing, acids and sugars stimulate taste receptors in the mouth, producing perceptions of sourness and sweetness. For a sense that is so crucial to both our survival and our enjoyment of life, it is remarkable that taste is so poorly appreciated. Perhaps this is because, after subtracting odor qualities (and other sensations such as pungency and various aspects of “mouth-feel”—see below) from the overall flavor of a food or beverage, we are left with a rather small group of sensory qualities—traditionally, sweetness, saltiness, sourness, and bitterness. This limited set of qualities is clearly inadequate to describe much of the sensory complexity of any cuisine. Compared to the rich, perhaps limitless, inventory of odors that contribute to the flavors in even an average diet, the sense of taste initially seems remarkably unimpressive. Yet, in forming the essence of any flavor, taste supplies information that is crucial to our survival and well-being.

### Basic Tastes

Taste is usually considered to be an *analytic* sense, composed of a key set of unique, indivisible qualities. In contrast to the *synthetic* sense of smell in which combinations of odors can produce a new quality entirely distinct from the components, tastes do not combine to form new qualities. Combining salt, sugar, and lemon juice may result in changes in the intensity of the tastes involved (different tastes typically suppress one another in mixtures), but it will only produce a mixture with the qualities of saltiness, sweetness, and sourness. As a result, these taste qualities, together with bitterness, are commonly talked about in terms of a set of *basic tastes*. It should be noted that this classification system is not without controversy but is adopted here, as it is the premise of most scientific literature on taste.

### Taste Perception

To be perceived as a taste, a chemical compound or food ingredient has to be soluble (for example, in water or

saliva) in order to reach the taste receptors. These are located within 3,000 or so taste buds, which are themselves located within structures on the tongue called *papillae* (although there are also small numbers of taste buds in other parts of the mouth). The most numerous of these structures, the *fungiform papillae*, are apparent as tiny bumps on the tongue's front upper surface. The *circumvallate papillae*, larger structures arranged in a chevron pattern, are located further back on the tongue, while the *foliate papillae* occupy the tongue's sides. Contrary to popular belief, taste buds are not specialized according to tongue location—we are capable of perceiving all tastes at any tongue location where taste buds are present (although our sensitivity to detecting different tastes does vary somewhat across different locations). The commonly seen tongue map, showing salty and sweet perception at the front of the tongue, sour at the side, and bitter at the back, results from a prolonged misinterpretation of the outcomes of studies published in 1901 by the German psychologist D. P. Hanig. In fact, lack of anatomical specialization for the different qualities is a characteristic of the taste system.

How a dissolved chemical compound becomes converted into a perception of, for example, sweetness or sourness, is increasingly understood. A large number of taste cells occupy every taste bud, extending their finger-like microvilli towards the pore through which the tastant compound will enter. For each taste quality, the microvilli of a cell contain different receptor mechanisms, which are responsive to the chemical structure of the tastant. Sodium and some other ions (potassium, calcium, and lithium) interact directly with channels on the membrane of the microvilli, entering the cell and producing biochemical changes that result in a nerve response interpreted by the brain as saltiness; the hydrogen ion ( $H^+$ ) in acids is similarly responsible for sourness. Bitterness and sweetness are thought to bind to specific receptor proteins on the surface of the microvillar membrane, and it is this binding that initiates the biochemical changes within the cell.

Unlike sourness and saltiness, sweetness and bitterness can be produced by substances belonging to a wide variety of chemical classes: not only sugars, but some proteins and amino acids are sweet. Other amino acids are bitter, as are alkaloids and some salts. This diversity appears to be reflected in multiple receptors for each of these qualities, although whether we perceive different types of sweetness and bitterness is currently under debate. Once the neural signals reach the brainstem, carried by the VIIth (chorda tympani), IXth (glossopharyngeal) and, to a lesser extent, the Xth (vagus) cranial nerves, there is still no direct relationship between quality and anatomy. Taste cells in the brain respond best to some qualities (“salt best” or “sweet best,” for example) but will in general respond somewhat to each of the basic qualities. This has led to the view that taste is coded (identified) in the brain through a pattern of responses across many taste cells.

In addition to the four well-known qualities, there is now considerable evidence for the existence of another basic taste, known as *umami* (pronounced oo-ma-me). This Japanese word, translated approximately as “savory deliciousness,” refers to the quality of foods containing significant amounts of naturally occurring glutamate (a derivative of glutamic acid, an amino acid), its sodium salt, monosodium glutamate (MSG), or 5'-ribonucleotides. *Umami* quality is perhaps most evident in the taste associated with rich sauce or soup bases made from stocks, mushrooms, or tomatoes. Adding Parmesan cheese to pasta provides another means of increasing the *umami* quality of the dish, as do many of the manufactured sauces throughout the world, for example, soy sauce. The status of *umami* as a unique taste derives not just from this quality being perceived as distinct from the other four basic tastes, but also from evidence for the existence of both glutamate receptors within the tongue's taste cells, and cells within the brain which respond preferentially to the *umami* taste. Very recent evidence has also pointed to the existence of taste receptors that respond broadly to many of the other amino acids (twenty in total) that make up proteins.

### The Hedonic Properties of Tastes

A limited set of basic tastes suggests that each of the qualities must be significant in some way. Why have we evolved to be sensitive to these qualities specifically? The answer lies in our hedonic responses to tastes. If our imprecise use of the word “taste” reflects our confusion about the different qualities that make up flavors, then perhaps in compensation, our language also provides clues as to the role that taste plays. In addition to describing food qualities, we also talk about tastes as a way of indicating good or bad aesthetic judgment, and we say that someone is bitter, or sweet, or has a sour face. Our use of taste qualities to describe such positive or negative emotions or qualities unwittingly reflects the underlying structure of the taste experience itself. In providing a hedonic basis to food and beverage flavors, taste functions as a built-in arbiter of what is good and bad in those things that we consume. As Brillat-Savarin noted in his gastronomical meditations (*The Physiology of Taste*, 1825), taste can be reduced “in the last analysis, in the two expressions, agreeable or disagreeable.”

In contrast to our preferences for odors, which are molded by exposure and reinforcement from an early age, hedonic responses to pure tastes are remarkably fixed. Distinct hedonic responses to sweetness and bitterness are present at birth, and are essentially the same as those we experience as adults. Both in terms of amounts ingested, and also in terms of their ability to elicit characteristic facial expressions, sweetness is highly liked and bitterness rejected in human neonates. Sourness also seems to be disliked. A preference for saltiness, on the other hand, develops in the first few post-natal months. While MSG in solution is not well accepted by neonates

(or, indeed, adults), soups to which it is added are preferred. These hedonic responses to pure tastes also seem to be relatively independent of culture or diet. Comparisons across cultures whose diets are very different, for example, Japan, Taiwan, and Australia, have found highly similar patterns of likes and dislikes for pure tastes.

**The significance of taste hedonics.** Whether as a genetic predisposition, or as a result of *in utero* influences, the origin of relatively fixed hedonic responses to pure tastes appears to lie in an adaptive capacity to respond appropriately to the nutritional implications of these qualities. Taste palatability, and ultimately the palatability of foods, seems to reflect either provision of energy, an individual nutritional need, or a warning of the presence of a potential toxin.

Sweetness is thought to signal the presence of energy in the form of calories provided by sugars and other carbohydrates, which are crucial to survival. Sweetness is thus a positive quality, reflected in its universally high palatability. This palatability is mediated by opioid (morphine-like) biochemical receptor systems in the brain, which are thought to be the biochemical basis for reward. This explains why sweetness can sometimes act like an analgesic, reducing crying in infants, for example.

Saltiness acts as a survival cue, by signaling the presence of the sodium ion (Na), necessary for maintaining the body's fluid balance. A liking for salt, while present at all times, grows substantially if we are deprived of it below what is physiologically necessary. Although there are many claims that cravings for various foods and nutrients exist, that for salt is the only one that is well-documented in humans.

The strong dislike that we naturally have to bitterness is thought to be a protective mechanism. Many plants manufacture toxins as a defense against predators, and very many of these toxins are bitter. Not surprisingly, then, we tend to be extremely sensitive to bitterness. However, as a result, we often reject levels of bitterness that are not in fact toxic to humans—witness the common fate of the poor brussels sprout. The significance of our dislike for high levels of sourness is not as clear-cut. It may be a signal for unripeness/spoilage in foods, or the fact that concentrated, and thus extremely sour, acids can cause tissue damage.

Because glutamic acid is an amino acid present in proteins that we consume, it has been suggested that the *umami* taste of glutamate acts as a signal for the presence of protein, thus promoting consumption. However, preference for *umami* actually seems to be strongest when protein intake is within normal limits. Alternatively, since dietary glutamate is involved in crucial metabolic processes and may possibly be used as an energy source within the gut, it may be that our preference for additional glutamate in foods reflects the importance of these functions.

## TASTE AND SMELL DISORDERS

The loss of our ability to smell or taste is perhaps not as immediately debilitating as the loss of the senses of vision or hearing, but such disorders can nevertheless have a profound impact on people's lives. The enjoyment of foods, beverages, perfumes, and nature, and our ability to avoid spoiled foods and environmental toxins, depend upon the proper functioning of these systems. Chemosensory disorders are also relatively common. As a conservative estimate, up to one percent of the population have some degree of smell or taste loss or disturbance. Given that alterations in the flavor of foods are the most immediate consequence of smell loss, it is not surprising that problems with "taste" are the most common chemosensory complaint.

In fact, complete loss of the ability to taste is rare mainly because, as a sensing apparatus, taste is highly redundant. Unilateral damage to the cranial nerves carrying taste information can eliminate sensitivity to taste on half of the tongue, but appears to produce few noticeable changes in our ability to appreciate tastes. Likewise, taste is able to survive even severe trauma to the tongue. *Aguesia* (total inability to taste), when it does occur through illness or accident, is reported to have devastating consequences in terms of food acceptability, food intake, and, consequently, physical and mental health. *Dysguesias*, or distortions of taste sensations, are, however, not uncommon. These, and partial taste losses (*hypoguesias*), can result from disorders of oral health, dental procedures, and some commonly prescribed medications (including antibiotics, antidepressants, anti-hypertensives, psychiatric drugs, analgesics, and chemotherapy agents). Neurological disorders such as Alzheimer's disease, renal and liver disease, diabetes, and viral infections have all been reported to be associated with taste losses or distortions.

The list of diseases associated with partial (*hyposmia*) or complete (*anosmia*) smell loss, or smell distortion (*dysosmia*) is even more extensive. Significant losses are reported in renal and liver disease, HIV infections, thyroid illness, epilepsy, Alzheimer's, and Parkinson's diseases. Most commonly, though, smell losses are associated with both acute and chronic diseases of the upper respiratory tract (including colds and influenza), nasal sinus disease, and allergies. Five percent of victims of head trauma also have some degree of smell loss. In cases of severe head trauma, smell loss is often complete

and irreversible, resulting from a shearing of the olfactory nerve fibers at the point where they enter the brain through the base of the skull.

Olfactory functioning is also susceptible to environmental toxins, making smell loss an occupational health issue. A variety of compounds used in manufacturing and other work environments, including metal dusts such as those of cadmium and nickel, solvents (acetone), and irritant gases (formaldehyde) have been implicated as causes of smell loss, particularly with long-term exposure. Cigarette smoking is known to produce chronic decreases in olfactory sensitivity, although this tends to recover once smoking is given up.

Diseases that affect smell and taste tend to be more prevalent as we age, as does the taking of medications that can produce deficits. Beyond these causes, however, we can also look forward to a "natural decline" in our ability to detect and identify smell and taste qualities, and a lessening of their impact. Using a 40-item "scratch and sniff" odor identification test, Richard Doty and colleagues at the University of Pennsylvania Medical Center showed that in both men and women, odor identification is reasonably stable until we reach our eighth decade. From this point on, the decline is fairly pronounced, corresponding to some extent to declines in vision and hearing during these years. Odors, and consequently flavors, are also less intense as we age, and our ability to detect subtle changes in intensity is reduced.

The sense of taste tends to survive aging somewhat better than our ability to smell. The threshold level at which tastes are detected increases, and taste intensity decreases, although not substantially, and not equally for all taste qualities—bitterness perception is particularly diminished. The ability to distinguish between different concentrations of tastants is also affected. Such losses, while not dramatic, can still have significant consequences. The levels of sweetness and saltiness that are considered by elderly people to be optimum in foods are generally higher, and food that is not adjusted accordingly may be considered bland.

One notable consequence of both smell and taste losses due to aging is that eating enjoyment is reduced. Particularly in institutionalized or hospitalized elderly people, this may exacerbate problems of anorexia and poor nutrition.

These seemingly distinct adaptive processes reflect an underlying principle on which the hedonic properties of tastes are based. Animal studies have suggested that

the palatability of any taste compound, and the responsiveness of taste cells in the brainstem, is strongly related to its toxicity. At one end of the spectrum are highly toxic

## MEASURING THE SENSORY QUALITIES OF FOODS

To produce foods that meet consumer needs, food manufacturers need to know the relative contributions of the various sensory qualities—tastes, odors, and textures—to the flavor of foods. Arguably, until this is known, it is difficult if not impossible to understand the consumer's responses to the product. Such information can be used to guide product development and ensure a quality product by allowing measurement of the effects of different production methods, changes in ingredients, and storage.

The process of describing and measuring the sensory qualities of foods and beverages is known as descriptive analysis (DA). To perform DA, small panels of typically ten or twelve individuals receive extensive training, often over a period of many months. During this time, the panelists learn to be consistent in their use of specific labels to describe sensory qualities. Such intensive training is necessary because of our generally poor ability to identify odors and flavors. Even with common food flavors, correct identification can be as low as 50 percent. Despite being able to say that an odor or flavor is highly familiar, we are often at a loss to identify the correct name. This has been labeled the “tip of the nose” phenomenon. In addition, to describe texture qualities, an entire vocabulary must be learned and applied appropriately. Fortunately, our ability to attach names to sensory qualities improves with feedback and practice. Importantly, too, training allows “concept alignment”—essentially an agreement as to the meaning of sensory descriptors and what constitutes examples of the concept. For example, the panel might need to agree that the term “lemon odor” refers to the odor of fresh lemon juice but not that of lemonade.

Providing labels for sensory qualities actually improves our ability to “see” those qualities in the midst of a complex food or beverage. To a novice wine drinker, a glass of sauvignon blanc tastes like white wine; with

experience, however, we learn that this wine variety often has odor “notes” reminiscent of asparagus or cut grass. Providing examples of these notes allows panelists to perceive these qualities within the wine. As a result, they are increasingly better able to detect that note each time they encounter this wine variety—in effect, panelists end up perceiving a collection of sensory qualities, whereas before they could only identify the taste as that of white wine.

Quantifying the intensity of those qualities that are identified is a key aspect of DA, allowing us to measure differences between products in a scientific manner. Training improves our ability to measure sensory qualities using rating scales. Measurements made with rating scales are always relative—they do not quantify an absolute quantity unlike, for example, measuring the concentration of a chemical compound. But they can nevertheless be used reliably with training. Moreover, there are no alternatives. No instrument yet devised can reflect the complexity of human perception.

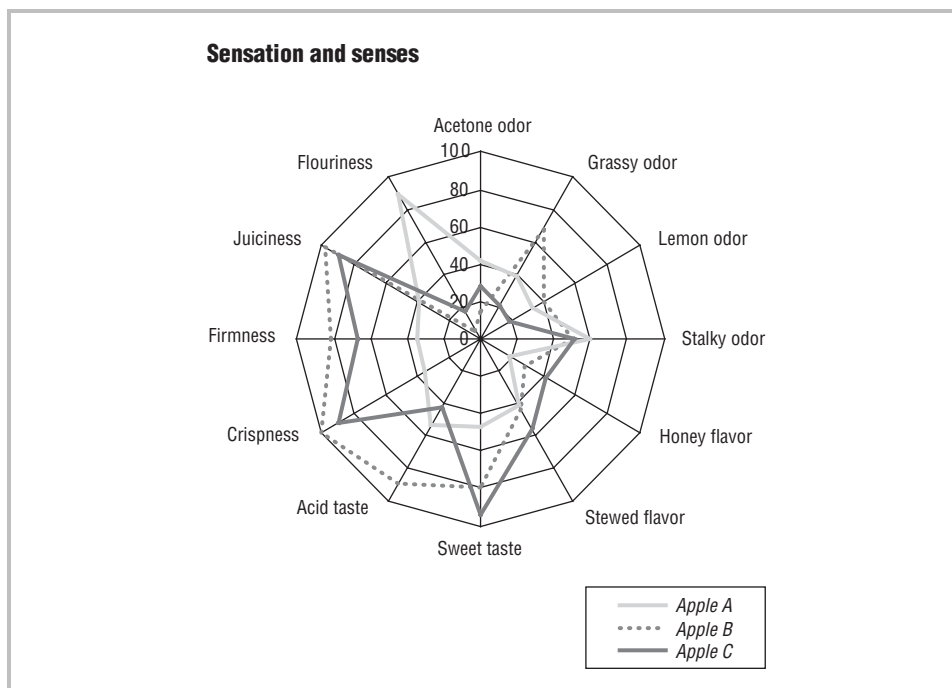

When developing these skills, trained panelists become less and less like consumers of the product. In fact, the aim is to have them approach the product in an entirely analytical way, which means ignoring any likes and dislikes and responding as though they were an instrument.

Once a panel is trained for a specific food, they are able to produce a flavor profile for a selection, or sometimes all, of the product's sensory qualities. In effect, this becomes the “sensory recipe” for that product. While flavor profiles say nothing about whether or not a product is liked, knowing the flavor profile of foods that are highly preferred can provide valuable information to guide future product development and predict the effects of variations in the sensory qualities.

compounds, which are rejected as unpalatable by both humans and many animals primarily due to bitterness; at the other end are highly nutritive substances with low toxicity that are well accepted, mainly because they are sweet. This neural and behavioral organization has led to the hypothesis that preferences for tastes are the method by which our bodies maintain their own physiological well-being. This makes considerable sense if our gustatory system is viewed as being at the interface between the external and internal environments. In this regard, we can view taste as being a “gatekeeper” whose function is to ensure that ingested substances maximize our sur-

vival. At least in this functional way, it is appropriate to talk about tastes as a continuum and to view sweetness and bitterness as opposites.

Consistent with the “gatekeeper” idea, regions of the brain responsible for processing information about tastes also receive neural information from the gut, and there is ample evidence of mutual interactions between taste perceptions and internal metabolic processes. Thus, metabolic states can modulate the palatability of tastes. The craving for salt when deprived of it has already been mentioned—but how does the body let us know it wants

A “spider-web” graph used to show the mean ratings given by a descriptive analysis panel for a variety of odor, taste, and texture attributes in three apple varieties. This provides a sensory profile of these apples, allowing study of their similarities and differences. Distance from the center of the web represents increasing intensity of each sensory attribute, so that Apple B has the strongest *grassy* odor, followed by Apple A, with Apple C being the least intense for this quality. GRAPH COURTESY OF SHANE WALKER AND HORT RESEARCH, NEW ZEALAND

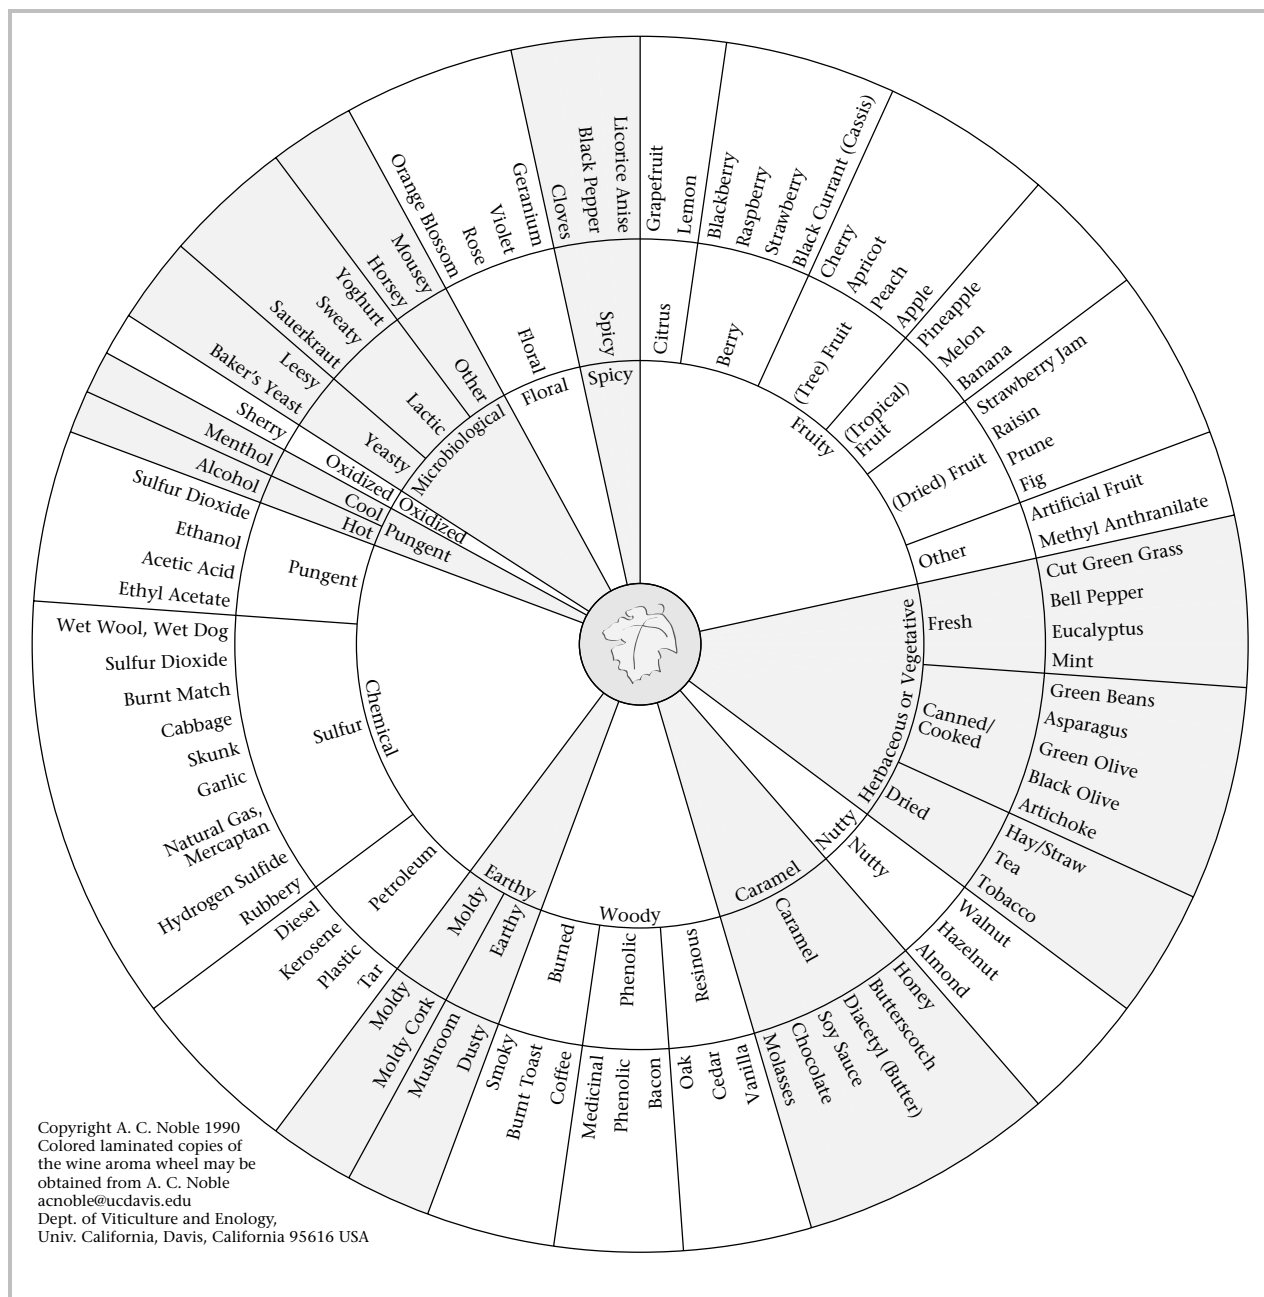

more salt? Studies in rodents have shown that “salt-best” taste cells in the brain actually decrease their responsiveness to salt following salt deprivation. Interestingly, however, this is accompanied by increases in the responsiveness of “sweet-best” cells to salt. This suggests that salt has become more pleasant, which would act to promote salt consumption to restore normal salt levels. In humans, too, the preferred level of salt in foods increases following salt depletion, and the rated desirability of salty foods goes up. This effect has also been shown for amino acids in cases of malnourished children and the elderly, in studies in which the addition of an otherwise unpalatable amino acid mixture increased the consumption of a soup. Similarly, animals fed a diet deficient in just one essential amino acid such as lysine will recognize its presence in foods, consuming them preferentially. Just the reverse seems to happen as a response to repletion. Sweetness becomes less pleasant following consumption of glucose, a phenomenon that is accompanied by decreased activity in “sweet-best” taste cells in the brain. Conversely, tastes are also able to influence metabolic processes, even prior to the nutrients’ absorption by the gut. These so-called cephalic phase responses include increases in salivation and secretion of gastric enzymes and insulin, changes that prepare one for receiving the nutrients and energy provided by foods.

### Chemesthesis: The Perception of Pungency

If the acidity in our apple is high enough, we might also perceive a degree of “bite” or “sharpness” due to activation of the free nerve endings of the Vth (trigeminal) cranial nerve. This nerve, which sends branches into the eyes, the nose, the mouth, and especially the tongue, transmits information regarding a wide range of tactile sensations, plus warmth, cooling, and even pain (think *very* hot curry). These sensations, often called pungency in the context of foods, are important to our appreciation of flavor in many foods and beverages. A cola drink without the fizz; the glass of wine without its sharpness; and onion, mustard, and horseradish without their bite or ability to induce tears have lost much of their defining quality. Whenever we talk about tactile sensations—stinging, biting, burning, numbing, tingling, or cooling—we are referring to pungent or chemesthetic qualities.

Trigeminally mediated sensations also very often contribute to the odors that we perceive in our environment. The eye-opening qualities of ammonia and many solvents derive from their ability to stimulate the trigeminal nerve as well as olfactory receptors. Not all such sensations are unpleasant. The cooling effects of peppermint, producing the pleasant illusion that our nasal passages have suddenly opened, are similarly mediated.

This wine aroma wheel shows how taste, sensation, and the senses are affected by various smells, flavors, and such taste components as saltiness, bitterness, and sweetness. For example, start from the center with fruity. Taste a wine and then narrow the fruitiness to berry or citrus (or both), then taste again to judge what flavor sensations are appropriate in the outer wheel. COURTESY A. C. NOBLE.

The trigeminal nerve also transmits information about temperature. It is not surprising then that chemically mediated chemesthetic qualities are modified by heating and cooling. The most obvious example of this is the ability of cool water to instantly eliminate chili-induced burning; conversely, this same burning is greater if the food is also (temperature) hot.

While pungent qualities are important sensory components of foods throughout the world, pungency is often associated primarily with cultures such as those of Korea, Vietnam, Thailand, and Mexico, whose cuisines use a lot of chili. These cuisines provide much greater flavor impact than typical Western diets, and their recent popularity in Western countries may reflect not just in-

creased availability, but a striving for new, intense culinary sensations. Even so, many people have reservations about hot (spicy) food. This is not surprising given that pain, oral or otherwise, is a clear signal to warn that damage has occurred or is imminent. The main heat-producing compound in chilies is capsaicin, a powerful irritant. However, despite common anxieties, there is no evidence that it damages otherwise healthy stomach linings or kills taste buds.

Even regular hot-food eaters complain, though, that if a food is *too* hot, appreciation of other aspects of flavor are spoiled or overwhelmed. On the face of it, it seems evident that such a strong sensation should overwhelm a weaker one. We are used to suppression of flavor and taste qualities by other flavors and tastes—for example, reducing the sourness of lemon juice by adding sweetness. Yet, the research evidence for this occurring with “heat” is fairly weak. When capsaicin (even at levels equivalent to a very spicy meal) is combined with tastes or odors in mixtures, only sweetness is reliably reduced.

The failure to find stronger effects of burning sensations is certainly contrary to popular belief and, perhaps, experience. Wine commentators, grappling with the question of what to drink with spicy food, commonly invoke the idea that hot foods overwhelm “subtle” wine flavors. However, it may be that burning sensations are simply a more prominent or memorable sensory experience since they persist long after the tastes and flavors have disappeared. Evaluating the intensity of something, we typically make comparisons (“sweet compared to what?”). Especially if the level of pungency is higher than an individual finds pleasant, this phenomenon might simply reflect the fact that the burn is intense and the flavor is not a “real” reduction of flavor intensity.

### Texture and Mouthfeel

Problems with texture are a common reason for rejecting foods. It is unlikely that we will finish an apple if it is either mushy or rock-hard. Our perception of many texture qualities relies on information from mechanoreceptors in the tongue, gums, and palate (also part of the trigeminal nerve) that detect the shape of food particles, together with pressure sensors in the jaw and gums. These sensors give feedback on how much force to exert in chewing, information that forms the basis for hardness perception. Compared to some other senses, hearing is perhaps of lesser importance in food appreciation. Nevertheless, the sound of the crunch when we bite into an apple allows us to fully appreciate its freshness and ripeness, and forms an integral part of our perception of its texture.

Sometimes in the past considered a taste, the property of astringency is now generally accepted as a set of *mouthfeel* sensations. Characteristic of foods and beverages containing tannins, including some fruits, nuts, tea, and cranberry juice, astringency consists of sensations of drying, puckering, and roughness felt on the mucous lin-

ing of the mouth. These sensations result when the tannins cause the lubricating proteins in saliva to precipitate out. Although it sounds largely unpleasant, astringency is a good example of how responses to sensory qualities are often highly dependent on context. While one of the reasons that we might not eat a green banana is that it tends to leave the mouth feeling like a sandpit, drinkers of red wine value these sensations, at least to some extent. When a wine is described as “dry,” the sensation is due to a significant extent to astringency.

Other textural sensations are produced by the water (for example, juiciness) or fat content of foods. Fat, in particular, is a key component of many of those foods that are highly liked, including red meat, desserts, cakes, chocolate, and dairy foods. Fat not only produces a sought-after texture, it is also an important carrier for flavor. Fat-reduced foods have often failed to be accepted because they were generally low in both flavor and textural properties such as creaminess. In addition to the desirable properties that fats create, liking for fat may actually be innate, because of its ability to provide energy (in a similar way to sweetness). This possibility is supported by recent evidence to suggest that fatty acids may have their own receptor—in other words, our bodies adapt to be able to detect fat. Given these considerations, it is not surprising that many people report that it is the sensory properties of low-fat foods that are responsible for poor compliance to dietary advice.

### Sensory Integration: What Are We Really Perceiving?

Despite the contribution from all of these senses, what we ultimately perceive—as opposed to the sensations we’ve experienced—is *an apple*. In his seminal *The Senses Considered as Perceptual Systems* (1966), the psychologist J. J. Gibson proposed that the purpose of perception was to seek out objects in our environment, particularly those objects that are biologically important. Nowhere is this more evident than in our perception of food qualities. Although we know implicitly that, while eating, a variety of signals are impinging on our gustatory, olfactory, tactile, visual, and auditory systems, this type of analysis does not come naturally. Thankfully, what we perceive when we sit down to dinner are “objects”—a steak and a glass of red wine—rather than a collection of distinct sensory signals. Moreover, likes and dislikes naturally spring from this synthetic mode of perception since we are responding to objects that we have learned to recognize as foods and that are therefore important to survival. Initial, “gut” responses to foods are almost always hedonic, and this naturally precedes accepting or rejecting the food.

The perception of food qualities reflects the integration of information from multiple sources. This is seen in the convergence of inputs from different sensory modalities in the brain. Edmund Rolls of Oxford University has described convergence of taste and odor information in what may be the physiological basis of flavor

## TASTE PERCEPTION: ARE WE ALL THE SAME?

"Now, anatomy teaches that all tongues are not equally provided with these papillae, and that one tongue may possess three times as many as another . . . the empire of taste also has its blind and deaf subjects." —Brillat-Savarin, *The Physiology of Taste* (1825)

Black coffee and beer are not only amongst the most commonly consumed beverages in many countries, they are also amongst the most commonly rejected by first-time users—primarily due to their bitterness. Clearly, preferences for initially disliked foods and beverages can develop. Repeated consumption itself tends to lead to increased liking. But why do some people more easily develop a liking for beer than others, and why, for some, does it remain unpalatable because of the bitterness? Research has begun to focus on individual differences in taste sensitivity as an explanation. While there have been some previous attempts to classify responses to tastes—for example, into those whose liking for sweetness tends to increase (sweet likers), versus those whose degree of liking flattens out or decreases (non-likers), with increasing concentrations of sweeteners—such classifications are poor predictors of food likes and dislikes. Recently, however, there has been a growing body of research that has investigated individual differences in taste sensitivity, the results of which have raised the possibility that these variations may be important influences on food preferences.

In 1931, A. L. Fox, an industrial chemist with the DuPont Company, reported the discovery that some people appeared to be "blind" to the bitterness of a compound, phenylthiocarbamide, or PTC. Subsequent research confirmed that this difference between individuals had a genetic basis, and it was initially thought that non-tasters might lack a receptor for PTC and other thiourea compounds. For several decades following Fox's discovery, the main focus of research was on this genetic basis, and how this might vary across different populations.

In the 1970s, however, this phenomenon began to interest taste scientists, in particular, Linda Bartoshuk from Yale University. Since then, our understanding of such genetic variations in taste sensitivity has grown considerably. Using a compound chemically related to PTC, 6-n-propylthiouracil (PROP), Bartoshuk and colleagues have demonstrated that each of us belongs to one of three groups—non-tasters, medium-tasters, or super-tasters—each varying in their response to PROP. Non-tasters, around 20–25 percent of the population (at least in Western cultures), find PROP tasteless, or very weakly bitter. Medium-tasters (approximately 50 percent) find PROP mildly to moderately bitter, while super-tasters (20–25 percent) find this compound almost traumatically bitter.

perception. He identified neurons in the olfactory area of the monkey cortex that responded specifically to qualities that occur together in flavors, for example, the sweetness of glucose and fruit odors. However, these neurons did not respond to incongruous combinations, such as saltiness and these same odors. Such neurons may actually start off responding only to odors and learn to respond to sensory combinations during repeated pairing of particular tastes and odors when they occur together as a flavor. Multimodal neurons in other sensory systems are thought to enhance the detection of, and reduce ambiguity associated with, external stimuli. In the case of odors and tastes, these neurons could help to resolve any ambiguity regarding the wisdom of consuming particular foods. Perceiving whole flavors, rather than distinct sensory signals, can be seen, therefore, as a survival strategy.

### Interactions within Flavors

The brain's integration of food qualities makes it difficult to discuss the different sensory systems in isolation from one another since these systems tend to interact. The way in which sensory properties like color can influence odors and tastes was mentioned earlier. Because sensory properties are perceived as aspects of the same

"object," we repeatedly associate the occurrence of one property with that of another.

In addition to setting up expectations for other sensory qualities to follow, learned associations between different qualities in foods can actually determine the qualities that we perceive. One of the most interesting examples is the ability of odors to rapidly form associations with other sensory qualities, especially tastes. In what appears to be the perceptual equivalent of the neurons described by Rolls, novel odors that are repeatedly experienced combined with a sour taste start to smell "sour"; those combined with sweetness start to smell "sweet." These effects are borne out in everyday experience. When asked to describe the odor of vanilla or caramel or raspberry, we will commonly use the word "sweet." This seems to be more than simply the fact that the odor recalls a food that was sweet since such odors can influence the intensity of that taste. Strawberry odor when placed together with tastes in solution can both enhance the sweetness of sucrose and reduce the sourness of citric acid, just as the addition of "real" sugar would.

Thus, our final perceptions receive input not just from a variety of sensory systems, but also from our mem-

Such findings would merely be of academic interest if it were not for the fact that, as observed so long ago by Brillat-Savarin, there is also considerable variation between individuals in the number of fungiform papillae on the tongue. In fact, different degrees of sensitivity to PROP are highly correlated with such variations in the density of fungiform papillae. Since individual papillae are not specialized for specific tastes, it is not surprising that those sensitive to PROP also tend to be sensitive to other bitter compounds, including caffeine and quinine, and also to the sweetness of sucrose, the sourness of citric acid, and the saltiness of common salt. The artificial sweetener, saccharin, is perceived as both sweeter and more bitter by PROP tasters than by non-tasters. Bartoshuk has suggested that, effectively, the different taster groups inhabit different taste worlds.

Although these are not taste qualities, PROP taster groups also vary in their perception of the texture of fats and the pungency of alcohol and chili. This is because fibers of the trigeminal nerve in the mouth, responsible for transmitting information on the majority of tactile and irritant qualities that we perceive in foods, tend to be anatomically associated with taste cells. So, the more taste cells that an individual has, the more trigeminal fibers they also possess.

These differences in taste *perception* influence how much tastes are liked, which ultimately produces differ-

ent patterns of food preferences. For example, coffee, spicy, and sharp-tasting foods such as some cheeses are liked more by non-tasters than tasters. Liking for cruciferous vegetables such as broccoli, cabbage, and brussels sprouts also appears to be related to variations in perception of their bitterness, and hence they are less likely to be consumed by PROP medium- and super-tasters than by non-tasters.

These relationships, apparent in both young children and adults, may turn out to be crucial in our understanding of food choice as it relates to disease risk. Increased consumption of cruciferous vegetables and reduced consumption of fats have both been linked to reduced risks for certain cancers. While the links between diet and diseases such as cancers and cardiovascular disease are increasingly being demonstrated, the notion that taste sensitivity could also predict risk has only recently been suggested, and may represent an important step in our understanding of susceptibility to dietary-related diseases. Sensory factors have frequently been implicated in the difficulties that we face in switching to healthier foods, e.g., lower-fat foods. These recent findings suggest that how successfully we are able to switch from a food containing a high level of sugar, salt, or fat to a version that is more consistent with health requirements may also be partly determined by genetic variations in taste sensitivity.

ory of past associations. In practical terms, it means that our perception of a quality like sweetness within foods will often include a contribution from a sweet odor and a sweet taste. Such phenomena also help us to appreciate that the sensory properties that foods possess derive not just from perception of their chemical constituents, but also from complex cognitive processes. Understanding these processes—even for the humble apple—requires inputs from a variety of scientific disciplines, most notably psychology, food science, neurophysiology, and molecular biology.

**SERVING OF FOOD.** The step between cooking and eating is far from insignificant. With sophisticated production and preparation, the serving of food involves important role divisions, etiquette, and cultural forms.

Such are the intricate social and cultural pressures that being served at an unfamiliar table or even just the arrival of an unfamiliar food can make diners uncomfortable. Families can fight over shares—the social struggle for resources in microcosm. But the serving of food is also a site of courtesy and generosity. Domestic hospitality depends on serving graciously, taking care of guests first, and offering second helpings. Professional waiters commit complicated orders to memory, return smoothly without mix-ups, perhaps conduct elaborate serving rituals, and note before anyone else any missing components.

### Types of Service

One logistical variable is the proximity of the cooking. This can be immediately in front of the diners so that the cook, host, or diners serve, at an adjacent kitchen as in restaurant waiter service, or at a distant factory when packaged snack foods are trucked to coin-activated machines. Serving can be done from staging posts, whether the immediate table, sideboard, dumb-waiter, trolley (as in the Hong Kong *yum cha*) or picnic basket. Diners sitting regally along only one side of a table enable service from the front; served from behind, dishes are conventionally offered from the left and taken from the right.

The number of diners changes the picture: from a handful of people around a campfire to thousands in dining halls, to vast street banquets, which have sometimes been served using bicycles.

Another key variable is the ratio of servers to diners. A ratio of one-to-one or even higher has enabled magnificent displays, vast tableaux, from which attendants could retrieve helpings on command. One waiter for ten diners or more can readily take orders and carry individual plates already made up in the kitchen. Even lower labor levels are needed for a cafeteria or hotel buffet, where diners help themselves and face the indignities of queuing.

The food itself is the most important variable. Dishes might require dressing, lifting, pouring, spooning, slicing or, most impressively, carving. In agrarian societies, eaters have helped themselves, or been served, from a common bowl or pot, but many meals involve two or more containers. The boxed Japanese meal called a *bentō* should display at least ten pretty items ready for the

### STYLES OF SERVING

**à la carte:** 'by the card'. The diner orders the progression of dishes beforehand from a menu or bill of fare typically showing the price of each item.

**service à la française:** 'service in the French manner'. Each course magnificently arrayed like a buffet, from which the diner or servant selects.

**service à la russe:** 'service in the Russian manner'. One dish at a time, either served at the table or already plated in the kitchen.

**table d'hôte:** 'host's table'. A common meal served at a fixed price, typical of an inn.

choosing. Sometimes diners have no choice, which is the case with table d'hôte (sharing the "host's table" typical of an inn), but a selection is often served. Chinese diners select food from the table and perhaps from a lazy Susan (central revolving stand). This can magnify into whole tables or "services" of food, which might even be changed through the meal as in the grand French style, *service à la française*.

The alternative, *service à la russe*, brings a series of dishes through the meal, perhaps carved in the dining room but often plated in the kitchen for each person, and is particularly associated with French-style restaurants. The food tends to be hotter and the meal to last longer. Individual choice is restored in restaurants with *à la carte*, that is, selections made previously from a menu or bill of fare.

The nineteenth-century debate about *service à la française* and *service à la russe* is not arcane, but reflects the broad historical trend from simultaneous serving to successive presentation, and from mass displays to individualized plates. The distinction is blurred, though, since many meals have been served sequentially, and the grand French spread (*le grand couvert*) already had several courses. Each plate in the modern Western style will probably carry several items.

### Server and Served

The sharing of food in meals gives serving its social significance. Meals also enable the sharing of roles, or division of labor, each person contributing what they can. Herein lies a paradox, for the very act of sharing food introduces a split between server and served.

Servers can take pride: Italian waiting can be highly skilled and as entertaining as any opera, French service so suave as to be hardly noticed, and the proverbially "resting" New York actors can demonstrate people skills.

There were several methods of serving food in the nineteenth century, the newest style being service *à la russe* (Russian style) shown here. This is the serving style employed by most modern restaurants, whereby the food is cut up into serving portions in the kitchen rather than at the table. Wood engraving from Alphonse Gouffé's *Royal Cookery Book* (London, 1868), copy of Charles Delmonico. ROUGHWOOD COLLECTION.

In a civilized society, people might take turns being served and serving. Jesus said he came “not to be served but to serve” (Mark 10:45 and Matthew 20:28). The Greek *diakonia* could mean “service” in a general sense, but Jesus meant the specific serving at table, his mission centered on table-fellowship.

However, serving has generally retained low status. “Beulah, peel me a grape,” ordered American actor-writer Mae West in her movie *I’m No Angel* (1933). The words “serve,” “service,” and “servant” derive from the Latin *servus* for ‘slave’.

When people began keeping livestock and other stored wealth, they introduced the concept of private property. Given that men made themselves the owners of the new sources of foodstuffs, this phase marked the “world-historic defeat of the female sex,” continues German social philosopher Friedrich Engels in the *Origin of the Family, Private Property and the State* (chapter 2, “The Family”) in 1884. The “woman was degraded, enthralled, the slave of the man’s lust, a mere instrument for breeding children.” She also cooked and served.

Women have often served men first—and larger shares than warranted by different body sizes and energy requirements—even at the expense of their own health. In *Cooking, Cuisine, and Class* (1982), British anthropologist Jack Goody notes that women of the Gonja of Ghana

distributed larger portions of cooked meat to men’s bowls. Even when the meat went into a common soup, he found that educated women held back, though the men “jokingly claim that if women do not help themselves beforehand, they are fools” (p. 68). The differential distribution of food between sexes shows up in modern societies, as Nickie Charles and Marion Kerr illustrate in *Women, Food and Families* (1988).

Friedrich Engels also argued (chapter 9, “Barbarism and Civilization”) that the increase in production with agrarian civilizations increased the demand for labor, which was furnished by captives of war made into slaves. The Roman propertied classes numbered their household slaves in dozens, sometimes hundreds, and they ran the meals. A crowd, typically male and properly attired, carried in the meal’s three to six courses. A contemporary observed that “all night long they have to stand around, hungry and dumb.” Real prestige belonged to the wine waiters—who were expected to be “young, smooth-shaven (but long-haired), and sexually attractive,” writes John H. D’Arms in “Slaves at Roman *convivia*” (1991).

To believe the satire of a nouveau riche banquet at the height of Nero’s Rome, described in the *Satyricon* of Petronius, the “boys” might make dozens of entrances, pouring out snow-cooled water, sprinkling the room with colored sawdust, carrying round bread, towels and hot

water, anointing the diners' feet, singing, clapping, and dancing. Elaborate carving was already well established, and Petronius describes a man slashing at a great platter of plump fowls, sows' udders, a hare and fish, with his hands moving in time to the orchestra, "like a charioteer battling to the sound of organ music." At the same feast, a whole boiled calf is demolished by a carver playing the warrior Ajax in a scene from Homer, sharing the pieces on the point of his sword among the surprised guests.

Slaves routinely had access to leftovers, but any concessions to conviviality have to be set against the fundamental powerlessness. Suetonius, a biographer of the Caesars, relates how Emperor Tiberius once publicly reprimanded the lecherous old spendthrift Cestius Gallus, while privately accepting his dinner invitation as long as the waitresses were naked. Humiliation and punishment (including murder) contrasted with the convivial setting. Again according to Suetonius, a slave stole a strip of silver from a couch at a public dinner, so Emperor Caligula had the executioners lop off the slave's hands, hang them around his neck, and take him on a tour of the tables.

Being a house rather than field slave could bring privileges in the American South. As Eugene D. Genovese notes in *Roll, Jordan, Roll* (1975), "servants trained and polished for elegant performance as butlers, cooks, and dining-room attendants were hard to obtain and not easily spared" (p. 329). But the household staff could also have less free time, have to snatch meals when they found a moment, miss out on plantation singing and feasting, and were continually reminded of their deprivation.

### Courtly Service

The recipes in the courtly English book dated around 1390, *The Forme of Cury* [Cookery], begin "Take . . ." and usually conclude "serve it forth" or "*messe* it forth." The word *mess* has referred to a portion of food, a liquid food, a made dish, and a course of foods, all of which had been "messed" forth—from the Latin *mittere*, 'to send'. Those sitting together at a banquet and sharing from the same dish were called a *mess*.

The officers in grand medieval households, where regular diners numbered in the hundreds and even thousands, included the ewerer who carried washing water and towel, the cupbearer who fetched wine, the butler who supervised butts of wine and ale, and the surveyor who controlled the surveying board to which the cook directed the platters. The carver's was still an exalted domestic station, with intricate rules to "break" that deer, "display" that crane, *alay* that pheasant, *tranche* (slice) that sturgeon, and so forth. Madeleine Pelter Cosman writes in *Fabulous Feasts* (1976) that the titles, responsibilities, and implements of food service could be carried by noblemen and sons of gentlemen. Serving could prove a means for political and professional advancement; Cardinal Morton predicted that the young Sir Thomas More, who was waiting on him, would prove a marvelous man (p. 26).

The disappearance of public carving in stylish European culture was accompanied towards the end of the nineteenth century by the switch from service *à la française* (each course or "service" arrayed like a buffet) to service *à la russe* (one dish at a time). With the cook often "plating up" behind the kitchen door, the mealtime distribution of food was moving to the back room and from the hierarchical to the individualistic. This reflected the shift in power from the aristocracy to the business class, and their more private meals.

This rationalization of food serving was supported by Thomas Walker, the London essayist of "aristology" (the art of dining). Devoting much of his 1835 weekly newspaper, *The Original*, to what he calls "attendance," Walker protested against the "cumbrous" ceremony of service *à la française*. Servants would take each dish on a circuit, and the wines move "languidly round two or three times." He favored service *à la russe*. "I like the familiar and satisfactory style both of cooking and of eating, with the dish actually before me on *mensa firma*, the solid table—not a kickshaw poked from behind, and dancing in the air between me and my lady neighbour's most inconvenient sleeve, without time to think whether I like what is offered." A small party of eight should assemble, and every dish be "served in succession, with its proper accompaniments, and between each dish there should be a short interval, to be filled up with conversation and wine, so as to prolong the repast as much as possible, . . . time would be given to the cook, and to the attendants."

### Self-Service

If not enforced by marriage or slavery, household servants have been tied through affective, material and financial dependence. The smaller households late in the nineteenth century had just one or perhaps two live-in domestics, a cook and a maid. However, the employers confronted a "servant problem," because many young women preferred more public work as shopgirls. This helped stimulate the feminist dream of "kitchen-less" homes reliant on central facilities.

If the keynote of the nineteenth century was the reduction in servants, that of the twentieth was the effort to displace serving entirely. The "service industries" took over more roles of a servant with less labor. The factory took over more finished food preparation. Costs might also be reduced by "self-service." In the cafeteria, a line of customers might choose items, place them on a tray, and carry them to the cashier. Oddly, this was like a return to service *à la française*, without assistance.

McDonald's has become emblematic of casual, deskilled, and formulaic service. In 1948, at the drive-in restaurant of the McDonald brothers, Dick and Mac, at San Bernardino, about fifty miles east of Los Angeles, twenty young women waiters called "carhops" served up to 125 cars from the twenty-five item menu, featuring beef and ribs cooked in a barbecue pit fuelled with

hickory chips. But the brothers faced increasing competition and labor and advertising costs, so they sacked their carhops, slashed the menu, halved the price of a hamburger to an unheard-of 15 cents, abandoned china and flatware in favor of paper bags, wrappers and cups, organized industrial kitchen equipment, and adopted rigid operating procedures to “eliminate the principal obstacle to fast-food service—the human element,” corporate historian John F. Love observes in *McDonald's: Behind the Arches* (1986, pp. 11–18). The brothers put an “industry that prided itself on extremely personalized procedures” on the assembly line. Under subsequent owners, McDonald's introduced the world to the inane-sounding, “Have a nice day.”

Having meals in company requires the serving of food, but this can become exploitative and inequitable. One answer is a “help yourself” culture of individualized service, but generosity is maintained when people take turns as server and served.

**SEX AND FOOD.** Food and sex are inextricably linked. Feeding insures survival of the individual while sexual activity insures survival of the species. Beyond biology, making love and eating share psychological attributes as two of life's greatest pleasures, both capable of providing a sense of nurturing, comfort, and being loved as well as instant gratification. Paradoxically, the two drives can also be the source of much psychological conflict, guilt, and shame. They generate anxiety in many cultures, partly because these are traits we share in common with animals.

#### Speaking of Food and Sex

The language we use to describe sex and food is very similar. In *The Rituals of Dinner* (p. 18), food anthropologist Margaret Visser describes a meal as a ritual in which “desires are aroused and fulfilled.” We speak of fat, in particular, with sexual connotation—words like “juicy,” “tender,” “satisfying,” “greasy,” “soft,” “great mouthfeel.” In popular culture, the semantic commonality and double entendres are even more pronounced. A T-shirt sold in New Orleans, for example, displays a picture of a Louisiana oyster with the words “Eat me raw” (Schell, p. 203). The pages of women's magazines are largely filled with articles on food or sex with a typical headline reading “The Next Best Thing to Sex is . . . Chocolate.” Advertising plays on sensuality in promoting acquisition of food products. Häagen-Dazs premier ice cream, for example, has run a campaign based on the tagline “Too much pleasure?” Best-sellers using food as a theme, including such sensual novels as *Chocolat* by Joanne Harris and *The Mistress of Spices* by Chitra Banerjee Divakaruni, as well as memoirs with erotic elements such as *Aphrodite: A Memoir of the Senses* by Isabel Allende and *Comfort Me with Apples* by Ruth Reichl vie with self-help books about sex for top billing. In 1972, physician and sex expert Alex Comfort published his classic sex manual *The Joy of Sex*, a play on the title of the classic cookbook *The Joy of Cooking*. His approach of prescribing “recipes” for good sex was criticized.

#### Life's Greatest Pleasures or Pain?

Sigmund Freud blamed sexuality and the need to master and socialize sexual impulses as the root cause of psychological angst. These feelings, he reported, began at birth. He described sexual response in nursing infants, tracing the arc of sexual arousal and fulfillment, flushing of the skin, and sleep following the satisfaction of feeding. More recently, food psychologist Paul Rozin of the

University of Pennsylvania theorized in *Social Research* (p. 9) that Freud would have had a stronger case making eating the culprit in the clash between biology and society. The feeding drive, he argued, is more frequent, urgent, and crucial to everyday life and human evolution than sexuality.

A love affair that ends can provoke great pain. Similarly, in some cultures, eating too much and gaining weight can undermine self-worth and compromise chances of finding a sexual partner. Much overeating is conducted in secret, just as sex often takes place behind closed doors. It is interesting that some people, not necessarily overeaters, suffer from a social phobia in which there is a fear of being watched or humiliated while eating a meal. This phobia provokes such overwhelming anxiety that it is impossible to enjoy the pleasure of going to a restaurant. Both sex and food are associated with physical as well as psychological danger—namely the morbidity and mortality consequences of obesity, food-borne illnesses and bioterrorism as well as the risk of contracting sexually transmitted diseases (STDs) and autoimmune deficiency syndrome (AIDS).

### Sexual and Feeding Appetite

To some extent, appetite for both sex and food increases with variety. Some fad diets succeed temporarily because they reduce the number of permitted foods, a restriction that presumably suppresses appetite. It is interesting to note that as variety and availability of foods, particularly imports, has increased in the United States over the past one hundred years, so has obesity. Among males, at least, a new or novel sexual partner can stimulate a sexually spent male to copulate again. This novelty effect, also known as the Coolidge effect, is not true for females, according to the newsletter of the Human Behavior and Evolution Society. Sexual appetite may be suppressed in a long-term monogamous relationship with a familiar partner.

### Across Cultures

Anthropologists have long studied how sex and food intersect in less developed cultures. Among the Langkawai, a Malay island culture, kinship is defined by “incorporation,” the process of neutralizing differences between people by taking in (“incorporating”) some of their “foreign” substance, food or sexual fluids, through the rituals of feasting and marriage. Both acts serve to convert the Other, someone unrelated in this case, into kin, and therefore nonthreatening. In the Hua society of New Guinea, there is an implicit association between feeding and sexual intercourse in which one partner “feeds” the other. Both acts are believed to achieve the transfer of *nu*, the vital essence.

### Food Sharing: Key to Intimacy

Sharing food is a way of establishing closeness. There are profound differences among cultures in this practice. Re-

Cover logo for a men's magazine called *Hot Dog* (Cleveland, Ohio, 1925). The hot dog, a food icon, is transformed into a metaphor of sexual innuendo. ROUGHWOOD COLLECTION.

search has focused on heterosexuals, but there is no reason to think that the same principles would not apply to homosexual couples. In France, sharing of restaurant food between a man and a woman takes on a sexualized characteristic. It is a common flirtatious practice to eat out of each other's plates. In this playful exchange, each partner may be testing how far the other is willing to go toward greater sexual intimacy.

Research conducted by Miller, Rozin, and Fiske has found that, in the United States, at least, college students perceive variations in food sharing as revealing the level of intimacy. The students viewed videotapes of opposite-sex couples sharing food in one of three ways: (1) simple sharing, such as passing a dish; (2) feeding the partner from his or her plate by hand or utensil; or (3) offering food from which one has already taken a bite or lick. The observers were asked to assess which couples, were involved in a sexual relationship. Those who practiced “simple sharing” were perceived as nonsexual friends; the couples who either fed each other or exchanged already sampled food were perceived as sexually involved. Across cultures, offering and accepting food that has already been eaten or licked (like an ice cream cone), meaning that it is potentially “contaminated” by saliva and germs, is often perceived as limited to people who are intimately related. There is a survival rationale—the saliva

of someone one does not know is more likely to contain dangerous foreign germs.

Courtship feeding among couples is common, ranging from the proverbial Valentine's Day gift of a box of chocolates, to the dinner date as a prelude to sexual activity, to preparation of dinner or food gifts for a potential lover. Food here serves as foreplay. A sensual experience in the eating sphere is expected to lead to one in the sexual sphere.

### Gender Differences

In most cultures men and women generally occupy prescribed gender roles in the arenas of both food and sex. The women's movement aside, females are still most often expected to be the "cooks," the presenters of enticing tidbits which may be themselves, while men are the consumers. In homosexual relationships, one partner may self-select to assume the more traditional female role. Beginning in the early twentieth century and well into the 1960s, many U.S. cookbooks offered women culinary and sexual/marital advice side by side. In 1962, food writer Mimi Sheraton suggested in *The Seducer's Cookbook* that a woman use her culinary wiles to lure a man into the bedroom. In 2001, British television cook Nigella Lawson was still perpetuating gender stereotypes in her book *How to Be a Domestic Goddess*. At the same time, the media have discovered the macho sex appeal of many male chefs such as Ming Tsai, Marcus Samuelsson, and Anthony Bourdain, who may well be alluring to both sexes.

Women in many cultures are still encouraged to deny their hunger and desire both for food and sex. In various cultures at different points in time, slender bodies have been idealized in an apparent attempt to restrain women's sexual desire. Historian Carol Groneman notes that in eighteenth-century France, nymphomania was thought to be caused by, among other things, eating rich food and/or too much chocolate. Paradoxically, while being told to restrain their desires, women are at the same time expected by most cultures to provide food and sexual pleasure for others. This contradiction has been blamed by some feminists for the preponderance of low sexual desire and eating disorders among women.

That women at least are judged both morally and sexually on the basis of what they eat was demonstrated in a unique experiment at Arizona State University in 1995. Subjects were asked their opinions of the morals of two fictional twenty-one-year-old women of the same height and weight, based on their diets. The first "Jennifer" ate fruit, salad, homemade whole wheat bread, chicken, and potatoes. The second favored steak, hamburgers, French fries, doughnuts, and double-fudge ice cream sundaes. The Jennifer who ate the lean, healthy diet was perceived as moral, feminine, attractive and sexually monogamous. The second was labeled immoral, inconsiderate, unconcerned, and sexually promiscuous.

### Sexy Foods

Particular foods—often high in fat and sugar, like chocolate—have come to be specifically associated with sexuality. In nineteenth-century Glasgow, Scotland, when ice cream was introduced by Italian entrepreneurs, it was blamed for loosening the sexual mores of the young. The fact that this rich treat was served in a new kind of public eating establishment, a café, patronized by unchaperoned adolescents, was part of the threat. However, Francis McKee in his paper "Ice Cream and Immorality" designated the ice cream itself, with its overtones of the forbidden and of sexuality, as at the root of the fear. Other foods are considered erotic because of their physical resemblance to sexual organs. Shellfish such as mussels and clams are said to look like female genitalia. Sausages, hot-dogs, and corn on the cob are often the subject of jokes based on their phallic appearance.

### Rules for Sex and Food

The lure of unrestrained enjoyment of food and sexuality for their own sakes has evoked a long history of cultural tension. Societies that fail to limit the expression of these biological drives are often considered doomed. The fall of Rome is typically depicted as a consequence of excess—too much sex, food, and wine consumed at the nightly orgies of the wealthy. Few cultures tolerate such freedom of expression. Consequently, taboos, moralizing, and laws are imposed to control and "civilize" the drives. Christianity has identified gluttony and lust as two of the classic "seven deadly sins." The number-one food proscription, across cultures, is the taboo against cannibalism. The equivalent in the sexual sphere is the incest taboo. It has been noted that the first has been more successful than the second.

Urging people to strive for slimness for health and aesthetic reasons has the effect of curbing the sensual pleasure of eating. So does the frequent emphasis on the health risks of certain foods. Attitudes vary widely from one culture to another. In a study of the attitudes toward food in four cultures—Japan, Flemish Belgium, France, and the United States—Rozin found that the French had the least concern about health consequences of high-fat food and placed the greatest premium on food's ability to enhance the quality of life. The moralization of food and lack of interest in its pleasure-enhancing effects is more typical of Western cultures, specifically Great Britain and the United States. Rozin has also noted that it is ironic that in America, where food is plentiful, the major maladaptive response is overconcern about health risks, with no thought given to the benefits lost in terms of quality of life.

**SHEEP.** If the dog is humankind's best friend, then sheep are its most ancient provider. Sheep may be the first domesticated ruminant, tamed by nomadic people in the Middle East and Asia 11,000 years ago, perhaps even before agriculture gave rise to civilization. Thousands of

years before sheep appear in the writings of Abrahamic faiths, they were slaughtered for religious rituals. Neolithic farmers, who raised them for meat, herded them into Europe. Wool breeds appeared at least 8,000 years ago, in plenty of time to supply the looms of ancient Egypt and Babylon. Vikings carried sheep to Iceland. The Spanish brought them to the Americas. Today, sheep are found from the Arctic region to Australia and in the tropics from Africa to the Caribbean. Yet the world's billion sheep are a modest source of meat. Humans eat ten times as much pork as lamb and mutton. Sheep is not a forbidden food, though. It is eaten readily by Hindus, Muslims, Jews, and Christians. And thanks to its global acceptance, lamb can be a gourmand's delight. Its earthy flavors blend well with the spicy seasonings of Spanish *asador*, Chinese red-cooked lamb, or just the smoke of an open-pit barbecue.

### Origins

Sheep, the species *Ovis aries*, are descended from the mouflon, an endangered wild sheep native to Asia Minor and Cyprus. The mouflon has a reddish-brown hair coat with an undercoat that is shed seasonally. Europe also has a mouflon that prefers rocky slopes of mountains and may have escaped from flocks of primitive domesticated sheep. Wild and domestic sheep and goats belong to the subfamily Caprini, which evolved ten to twenty million years ago in the mountains of Central Asia. They are in the order of mammals Artiodactyla, which means even-toed, hoofed. That order includes ruminant livestock such as cattle. Bacteria in the rumen help these animals digest cellulose in grasses. With more than two hundred domestic breeds, sheep may have the largest number of breeds that are in active commercial production.

In the United States, most sheep are eaten as lamb, animals that are less than a year old. Worldwide, much lamb, especially "spring lamb" slaughtered at three to seven months of age, is not grain fed. (In the United States, most lamb is grain fed, which gives it a milder flavor.) Lambs sold for meat usually weigh between 70 and 100 pounds, accounting for the relatively low rate of world lamb consumption as compared with other livestock. A mature market hog, for instance, is more than twice as heavy, and pigs are much more prolific. Adult female sheep, or ewes, weigh about 150 to 200 pounds while mature males, or rams, weigh about 250 to 350 pounds. Mutton, the meat of mature sheep, is more popular in Britain and Europe than in the United States.

### Methods of Consumption

In the developed world, sheep are processed and slaughtered in much the same way as cattle and hogs, in assembly-line, refrigerated packing plants. But in the tropics and deserts where they are still herded by nomadic people, they offer the advantage of being small enough to be consumed in a day, eliminating the need for refrigeration.

As with other meats, lamb's fat content varies with cooking methods and the cut of lamb chosen. Lamb loin chops, which correspond to pork loin chops and New York Strip steak in beef, are slightly leaner than either the beef or pork cuts, with 9.73 grams of fat in a 100-gram cooked serving trimmed to 1/4 inch fat and broiled, according to U.S. Department of Agriculture nutritional data. With 2 milligrams of iron, lamb has twice as much iron as pork, and nearly as much as the 2.47 milligrams in beef. Lamb is also a good source of phosphorus and zinc.

A comparison by the American Sheep Industry Association, a trade group, shows a 3-ounce portion of lean cooked lamb leg has 7 grams of fat, equal to that in beef round, less than fresh pork ham or chicken dark meat (both with 8 grams of fat), but more than the 4 grams of fat in chicken light meat.

The consumer group, the Center for Science in the Public Interest in Washington, D.C., lists lamb souvlaki at Greek restaurants as a relatively healthy food that compares favorably with other forms of red meat, at 310 calories and 11 grams of fat.

In a few less developed areas of the world, sheep are kept mainly for milk, or blood. A well-known vestige of sheep milking in the developed world is Roquefort cheese, made in France. Sheep's milk has almost twice as much fat as cow's milk (6.7 percent), but is denser in other nutrients as well, including calcium.

The main nonnutritional product of sheep is wool. Wool is one of the few fibers that will maintain body heat when wet. Wool also makes durable, fire-resistant rugs and carpets. Other widely used sheep products include skins and pelts for coats and rugs. Sheep lanolin, the purified grease that is washed from wool, is found in many cosmetics, salves, and ointments.

### **Nomadic Livestock with a Rich History**

Archeologists have found evidence of sheep domestication from about 11,000 years ago, in northeastern Iran. Sheep bones nearly as old have been found in Palestine. A small statue of a woolly sheep from about 6,000 B.C.E. that was found in Iraq shows that the development of wool breeds is also ancient. By 6,000 years ago, Egyptians and Babylonians were weaving spun wool into fabric.

Sheep appear in early religious and mythological writing and history. In Ancient Egypt, the ram was the symbol of several gods. In Greek mythology Jason pursued the Golden Fleece. The Abraham of the Bible and Torah sacrificed a ram instead of his son. Long before agriculture gave rise to civilization, human hunting cultures seemed to have worshiped animals. The 30,000-year-old paintings of animals at the Chauvet Cave in France include the ibex, a wild relative of goats. Perhaps because sheep were domesticated early, their slaughter became ritualized in religious ceremonies.

Sheep breeds have outlasted civilizations. The Merino, which has come to dominate high-quality wool production today in Australia, the world's top wool exporter, may date to the reign of the Roman Emperor Claudius in the first century C.E. Many in the sheep industry believe that the breed was developed then in what is now Spain when breeders crossed the Roman Tarentine breed with the Laodian sheep of Asia Minor. When the Romans reached Britain, other sheep breeds were already there. The Romans built Britain's first woolen mill in Winchester in about 50 C.E. In the centuries that followed the fall of the Roman Empire, both Britain and Spain dominated wool production. In Spain, selling Merino sheep without the permission of the king was a crime punishable by death.

Spanish monarchs did allow explorers to bring Merinos to the New World. The Navajo sheep in the United States and the Criollo of Latin America are their descendants. When slaves were brought to the Americas, African sheep breeds adapted to hot climates came with them. These breeds have a coat of shorter hair and do not produce wool. The West African Dwarf type of sheep gave rise to several tropical American breeds, including the Barbados Blackbelly. The Tunis breed of North Africa was two thousand years old when George Washington imported some to rebuild his own sheep flock after his presidency.

Sheep have long been herded by nomads in Central Asia. The portable dwellings, or yurts, of Mongolia are made of wool felt. In the fourth century B.C.E., the Chinese called the hinterlands of central Asia "the land of felt."

In contrast to tropical sheep, primitive sheep breeds from northern Europe have long outer wool coats of up to 15 inches in length as well as a soft inner coat. The Icelandic sheep, brought to Iceland by the Vikings in 874 C.E., are the purest breed of this type.

Modern sheep production began in the eighteenth and nineteenth centuries with two important developments. One is that the Spanish monopoly ended when Napoléon invaded Spain, making Merino sheep widely accessible. The other was the development of meatier breeds of wooled sheep in Britain in the eighteenth century by Robert Bakewell, an English agriculturalist who revolutionized the breeding of sheep and cattle through selection and inbreeding. At a time when wool prices were depressed, Bakewell began to select Leicester sheep that were heavier and stockier. This helped feed Britain's Industrial Revolution. Sheep were not herded long distances in Britain as they were in Spain, so the British Isles developed many more local breeds. Other breeders followed Bakewell's example of choosing breeds that have a dual purpose. In the United States, dual purpose and wooled breeds that excel in meat production are preferred in the eastern half of the country. The finer wool breeds are preferred for the western range because they are easier to herd.

Pansy, Vicky, and Lady Scott, prize black-top Spanish merino ewes bred in 1887. From the *National Stockman and Farmer* (February 7, 1889). ROUGHWOOD COLLECTION.

Though adaptable and hardy, sheep are more difficult to raise in the humid tropics. They are scarce in Southeast Asia and the islands of the South Pacific and even northern tropical Australia.

### Effects of Domestication

Domestication has changed sheep so much that they are almost helpless in the wild, according to animal scientists M. E. Ensminger and R. O. Parker, who in *Sheep and Goat Science* note that “domesticated sheep of all breeds are universally timid and defenseless and the least intelligent and least teachable of all the domestic four-footed animal. . . . Unlike other farm animals, they are unable to return to a wild life” (p. 4).

The Merino are among the most easily herded sheep. For centuries in Spain they were driven to northern pastures in the spring and back south in the fall. This resulted in selection for ease of herding. More primitive breeds remain more independent. Sheep farmers in Iceland often lose a few of their Icelandic sheep when driving them from summer mountain pastures to lowlands. One unusual type of sheep in Hawaii, the Feral Hawaiian, mostly of Merino stock, has confounded the experts by actually going wild. It was introduced in 1791 when Captain George Vancouver visited the islands.

### Trends in Sheep Production

Britain and Spain once dominated sheep production and trade. In the early twenty-first century, dominance has

shifted to former British colonies of the Southern Hemisphere. Australia ranks first in wool exports. Second-ranked New Zealand is a big exporter of carpet wool, mainly from its Romney breed, a native of English lowlands. Both nations are also top exporters of lamb. At the end of the twentieth century, Australia had 115.8 million head of sheep, slightly behind the world’s largest flock, 131 million head in China (where they are mainly for domestic use). New Zealand was third with 45 million sheep, followed by South Africa and Turkey. China is a leading importer of wool for its mills.

By contrast, the United States produced only about 7 million sheep and lambs in 2001, a sharp decline from the beginning of the twentieth century, when the United States had nearly ten times as many sheep—61 million head. U.S. wool production has fallen from 260 million pounds to 49 million in a century.

American agricultural practices and the rise of industrial fibers—plastic—contributed to this decline. The industry survived in Great Britain, partly due to European Union subsidies. In the United States, government subsidies rewarded eastern U.S. crop farmers who grew corn and soybeans instead of those raising small marginal flocks. Corn and soybeans then flowed to large, mechanized complexes for hog and poultry, which convert grain to protein faster than can sheep. In the western range land, the federal government dropped wool subsidies in 1996 only to reinstate them in 2002 in an attempt to help a struggling industry. Only about 1 percent of the meat

The French prepare a number of dishes using parts of sheep not commonly eaten in the United States. This salad of lamb brains was prepared at the Restaurant Guy Savoy in Paris. © OWEN FRANKEN/CORBIS.

consumed by Americans was lamb. By 2000 per capita lamb consumption in the United States was less than 1 pound per year, compared to an estimated 221 pounds per year of all red meats and poultry. Growing popularity of ethnic foods, along with immigration from Mediterranean nations that relish lamb, ensured a remaining niche market for this meat. But outside of large cities, many consumers had to hunt in grocery store meat cases for a package or two of lamb chops or perhaps a single leg of lamb.

Reasons for the decline in U.S. sheep production seem to be both economic and cultural. Competition from plastic fibers, including polyester fleece, which has some of the desirable properties of wool, has hurt demand for a key product from sheep. A booming economy in the late twentieth century contributed to the already tough task of finding workers willing to take on the solitary task of herding sheep on the western range.

American taste for lamb may have been hurt by bad experiences of American servicemen and women during World War II, who sometimes ate old mutton from Australia and New Zealand and mistook it for lamb. But the main factor is undoubtedly economic. With a small market for U.S. wool, and therefore lamb, the meat has become an exotic, more expensive specialty food. A similar decline has taken place in Canada.

North America has also faced stiff competition from New Zealand and from the Australians, who rival the Spaniards as finicky producers of fine wool, developing several strains of Merino breeds best adapted to their climate. Both Australia and New Zealand offer longer grazing seasons than the northern United States and Canada, giving those nations another advantage. New Zealand farmers can graze their sheep from eight to twelve months of the year and are world leaders in developing microchip-controlled electric fences to allow the most efficient use of pastures. A flock is moved into a small paddock where the sheep graze all of the available forage before moving into another small field. New Zealanders can raise twenty-five sheep on a hectare of land (2.47 acres) with this method.

Unlike American and European farmers, Australia's and New Zealand's sheep producers receive no large government subsidies, which keeps their farm economies lean, preventing artificial inflation of land prices that boost costs. As the twenty-first century began, both nations had an exporting advantage of lower-valued currencies compared to the American dollar.

Even so, the returns in 2002 on sheep production in Australia lagged behind those enjoyed by U.S. grain farmers, and in New Zealand, where there are a dozen sheep for every person, the sheep population has declined from a peak of 70.3 million in 1982 to about 45 million, "due to declining profits compared to other types of farming," explains a wool products website, Sheep World.

The biggest challenge to sheep may still be plastic. Australian researchers are looking for new ways to turn wool into a fabric without weaving—a response to a 10 percent annual growth in "nonwovens," synthetic fabrics used in car seats, home draperies, and disposable wipes. Ironically, felt, the original nonwoven material, was made from sheep's fleece before spinning and weaving were invented. If the wool industry can compete successfully with the plastics industry, the availability of lamb as a food might increase.

### A Case for Saving Sheep

From a gastronomic perspective alone, it would be a shame if sheep became extinct. Chefs Bruce Aidells and Denis Kelly argue in *The Complete Meat Cookbook* that lamb's flavor "makes this animal a favorite in cuisines all over the world. . . . No meat marries better with the pungent flavors of garlic, mustard, rosemary, thyme, oregano, savory and fennel, to name just a few" (p. 427). Among the world's most notable lamb dishes are Moroccan lemon *tagine*; kabobs (called *souvlaki* in Greece; *sis kebabi* in Turkey); and baked leg of lamb *asadar* from Spain (in Spain a whole lamb is roasted in a wood-fired brick oven).

Do-it-yourself gourmands should be aware of pitfalls. To avoid lamb's hard fat, which some people find disagreeable when it becomes cold, trim as much fat as is possible from lamb before cooking and be sure to keep lamb dishes hot at the table.

Other practical reasons for saving sheep include environmental ones. Although sheep were associated with some of the first human environmental degradation—soil erosion associated with overgrazing—properly managed, sheep can improve grasslands and range land. They will eat weedy plants that cattle ignore, including sagebrush, leafy spurge, and tansy ragwort. Some ranchers and wheat farmers consider them more effective at controlling plant pests than herbicides.

One serious problem that could instantly make sheep an unwanted food source is bovine spongiform encephalopathy, or BSE. Sheep may have been the indirect source of this dreaded affliction, known as mad cow disease. The incurable disease literally turns a cow's brain spongy, causing a progressive dementia that kills the animal. In Britain, rendered sheep, goat, and cattle not fit for human use were added to cattle feed to boost the protein content. Some scientists believe that a related disease in sheep, scrapie, somehow crossed the "species barrier" when the rendered sheep were fed to cattle in the 1980s. Scrapie, a rare but very old disease of sheep, has never been known to infect humans, but BSE apparently has killed Britons who ate infected beef. This family of diseases, which also includes chronic wasting disease in deer and elk, is poorly understood. The infectious agent is a prion, a type of protein that has no genetic material, like a virus or bacteria. Prions are extremely resistant to heat and antiseptics and can survive in soil for

years. Yet certain types of sheep seem to have a greater genetic disposition to scrapie than others.

European and British health officials are concerned that sheep in that part of the world may also have been infected with BSE, rather than normal scrapie. If so, it would have the potential to make European lamb unsafe to eat. Even though scrapie itself is not deadly to humans, the possible confusion of BSE in sheep with scrapie has led the United States to start a scrapie eradication program in domestic sheep. New Zealand and Australia are believed to be free of the scrapie as well as BSE.

Finally, the loss of sheep and lambs to competition from plastic fabrics and more industrialized meats would be a blow to the collective memory of human history and tradition. The Bible has more references to lambs and sheep than to any other animal. The blood of the lamb protected Jews during the first Passover. Muslims break the month-long fast of Ramadan with a meal of lamb and rice. And to Christians, the lamb is the symbol of Christ sacrificed on the cross.

As a result of the efforts of rare breed preservationists, hobbyists, and home wool spinners, it is unlikely that sheep will ever become completely extinct, even if their long-term commercial success faces challenges.

**SHELLFISH.** *See* **Crustaceans and Shellfish.**

**SHERBET AND SORBET.** Sherbet and sorbet are both frozen desserts. Sorbet is flavored syrup with a slushy texture; it is sometimes called a water ice, and contains no dairy ingredients. Sherbet describes a similar product, but contains milk. One definition, by the International Dairy Foods Association, states that sherbet should contain 1–2 percent of milk fat in the final product. Despite this, the word sherbet is sometimes colloquially applied to sorbets. Related recipes, such as ice milk, frappés, and granita (a grainy water ice of Italian origin) lead to further confusion.

In other countries, the definition of sorbet remains consistent, but that of sherbet varies considerably. In British English it means a class of children's candies, powders which give a fizzy sensation on the tongue, sweetened and flavored with lemon or other fruit. In the Middle East, sherbet is a chilled soft drink. The constants in these different foods are sugar, a sweet-sour flavor combination, and the idea (if not the actuality) of cool refreshment.

A complicated history of linguistic and culinary borrowing lies behind these definitions. Modern writers have despaired of untangling the subject. Liddel and Weir comment that it is almost impossible to define the word sherbet, because of a shifting background of common usage, local customs, and legislation.

Sorbets and sherbets in North America both start with sugar syrup. This may be specially made, but sugar and water are also naturally present in ingredients such as fruit juice, wine or milk and individual recipes allow for this. Flavors other than fruit are provided by infusing flowers, herbs, or spices in the base syrup. If too much sugar is present, the sorbet will not freeze properly. Large-scale producers, and those seriously interested in making sorbets by craft methods, measure the syrup concentration. The optimum is between 17–20° on the Baumé scale. Sorbets containing alcohol use a lower density of 14–17° Baumé. Although excellent sorbets are made using only sugar, water, and flavoring, some recipes require egg whites or gelatin. These act as stabilizers, especially in sorbets which melt quickly, or when fruits with a high pectin content (which affects texture) are used. Occasionally, egg whites are added as meringue, for instance in champagne sorbets.

Freezing by churning produces the smoothest texture, although at home a still-freezing method can be used. As the temperature gets lower, ice crystals begin to form, kept small and evenly distributed by churning or periodic beating. The ice consists of pure water, so in the liquid fraction of the sorbet, the sugar content becomes increasingly concentrated. Sugar lowers the freezing point of water, and prevents the mixture becoming completely solid. Alcohol also freezes at a lower temperature than water, which is why sorbets containing wine need a less dense syrup to achieve the same slushy texture.

In sherbet recipes, milk provides some water for the basic mixture. It also adds small amounts of lactose, pro-

tein, and fat, giving a slightly different texture and a creamier flavor. However, sherbet is usually a very low-fat product. Sherbets and sorbets feel colder in the mouth than ordinary ice cream. This is partly because of the lack of fat (which helps to make ordinary ice creams smoother on the tongue), and partly because of their high sugar content, which makes the mixture both freeze and melt at lower temperatures.

A granita has an even lower syrup density (9–10° Baumé), and is always still-frozen, allowing relatively large ice crystals to form in the mixture. Minimal stirring keeps these evenly distributed and of a regular size, giving a characteristic grainy texture.

How do the iced desserts of North America relate to the sherbet candies and drinks to the east of the Atlantic? A clue lies in the derivation of the words sherbet and sorbet. Ultimately they can be traced back to a medieval Arabic root *sharâb*. This originally meant a sweetened drink (the word syrup shares a similar derivation), but was later applied to beverages containing alcohol. It gave eighteenth-century English the term *shrub* for an alcoholic punch. A slightly altered Arabic form, *shabât*, emerged to denote sweetened, nonalcoholic drinks. This passed into Turkish as *sherbet*, a word which diffused into European languages. However, the Turkish pronunciation only seems to have survived in English. Southern European languages dropped the *b*, following the Italian form which emerged as *sorbetto* (Spanish, *sorbete*; French, *sorbet*).

The sherbet mixtures of Arabia, Turkey, and Persia have always been flavored syrups that are diluted with water and served chilled, a welcome refreshment in hot weather. In the past, ice or snow was stored in winter for summer use with these drinks. Sometimes the syrup was boiled to the point at which it formed a solid candy. A version of this is still to be found in Turkey under the name *gul sekeri* (literally “rose sugar,” although it is actually flavored with cinnamon). Popular flavors include lemon, pomegranate, flowers such as rose or violet, and herbs such as liquorice or mint. The importance of sherbet in the Middle East is apparent from evocative descriptions given by Roden (1970) and Shaida (1992).

In seventeenth-century Italy, *sorbetto* came to mean a flavored syrup frozen to a point at which the texture was obviously iced but not hard. In the past, these cooling ices were considered medicinal. In Italy, *sorbetti* were given to people suffering from fevers and malaria, a custom also recorded in Persia. It was the iced aspect of these drinks that became important for sorbets. Although they seem to have remained liquid throughout the eighteenth century, in nineteenth-century France, sorbets became chilled confections with a texture somewhere between a drink and a modern water ice, sometimes with added alcohol. As the century progressed, sorbets were served colder and colder, and at some point they became solid enough to be eaten with a spoon. The culinary ascendancy of the French during the nineteenth century must

Turkish sorbet vendor as depicted in Friedrich Unger's *Conditorei des Orients* (Confectionery of the Orient), published in 1838. Unger was royal confectioner to King Otto of Greece. COURTESY OF THE BAYERISCHE STAATSBIBLIOTHEK, MUNICH.

have led to the adoption of sorbet as a standard term in restaurant cookery, giving it a relatively fixed definition.

In English, the word “sherbet” retained the sense of a sweet drink throughout the centuries. It was made from fresh lemons, or perhaps mixed from chunks of flavored sugar candy which were already being imported in the seventeenth century. The drink aspect continued to be important throughout the eighteenth century. In London in the 1820s, a street seller of sherbet and soft drinks devised a powder of sugar, bicarbonate of soda, tartaric acid, and lemon flavoring. When mixed with water, this made a sweetened lemon flavored “sherbet” which effervesced as the soda and acid reacted to give off bubbles of carbon dioxide. By the early twentieth century, sherbet and lemonade powder had become synonymous, and candy manufacturers began to incorporate it into their products. Sherbet in Britain is now seen purely as this particular type of candy—cheap, usually lemon flavored,

and always effervescent. Sorbet has retained the sense of a water ice.

In North America, sherbet developed down the iced dessert route. The sultry summer climate of the eastern United States, together with the commercial exploitation of lake ice stored for summer use, must have stimulated demand for such refreshments. During the mid-nineteenth century, sherbet and sorbet seem to have been synonymous, both words indicating frozen syrup, often served with wine or another alcoholic drink poured over. The habit for serving them between courses at dinner is also recorded. How sherbet came to acquire the meaning of an iced dessert which included milk is obscure. Recipes past and present do not make matters any clearer. Household recipes from the early twentieth century use the word to describe anything from a coarse crystal water ice (similar to a granita) through a standard sorbet, to mixtures containing milk. Later sherbet recipes sometimes contain buttermilk or milk and cream.

By the mid-twentieth century, ice-cream companies were producing sherbets flavored with lemon, lime, orange, or raspberry. Orange sherbet seems to be the one which stands out in childhood memories. In the 1980s and 1990s, there was a renewed interest in sorbets. The idea of serving them between courses in restaurants enjoyed a revival, but most compelling was the fact that they offer a dessert with no fat or dairy produce involved. Flavors have gone beyond the traditional lemon, lime or champagne into vanilla or chocolate, perhaps so that the products compete more overtly with conventional ice-creams. Sherbet, on the other hand, seems to have slipped into a slightly old-fashioned, declass   niche. Neither product offers a serious challenge to premium quality ice creams in the affections of the American public.

Nutritionally, sherbets and sorbets do offer low-fat alternatives to ice creams. Their principal contribution to the diet is energy, and their syrup bases give them a relatively high sugar content and higher calorie count than dieters might suspect. The milk in sherbet makes a small, but not a significant contribution of protein, fat, vitamins, and minerals. Fruit-based sorbets and sherbets, provided the fruit has not been heated or processed for a long time, contain a little ascorbic acid (vitamin C), but large quantities would have to be consumed to make them a significant source. The role of these items in the diet is principally one of a pleasant refreshment and light dessert.

**SHROVE TUESDAY.** The day immediately preceding Ash Wednesday, the beginning of Lent in the Christian churches of the West, is known in English as Shrove Tuesday. It occurs between 2 February and 9 March, depending on the date of Easter. The day takes its name from "shriving"—the pre-Lenten confession and absolution of the faithful as a preparation for Lent that was common in the European Middle Ages. Feasting on foods initially prohibited during Lent, such as meat, eggs, and milk products, was integral to Shrove Tuesday observance. The German term *Fastnacht* and the Dutch *Vastenavond* (eve of the fast) refer to the Lenten fast about to begin, while the French *mardi gras*, the Italian *martedì grasso*, and the Portuguese *terça-feira gorda*, all meaning "Fat Tuesday," refer to the feasting on foods rich in fat prior to the austerity of Lent. The Spanish term *martes de carnaval* (Carnival Tuesday) possibly reflects the formerly rigorous Lenten abstinence from meat commencing on Ash Wednesday and lasting through the forty days of Lent. The word "carnival" is thought to derive from Medieval Latin *carnem levare*, which means 'to take away or remove meat'.

The historical origin of carnival celebrations is obscure. The word "Lent" derived from Anglo-Saxon *lencten*, denoting the spring season. It may be, therefore, that carnival had its roots in an ancient spring festival or pagan agricultural rite marking the transition between winter and summer. Aspects of such ancient festivals are thought to be reflected in modern carnival celebrations connecting the change in nature with social and biological renewal. Thus, temporary social transformation, masking, processions, erotic dances, eating, and drinking still characterize carnival celebrations in much of Europe. The ludic element—the public, communal revelry—remains in the fore in carnival celebrations in the United States, especially in the New Orleans Mardi Gras, and in Brazil in the famous Rio de Janeiro Carnival.

In Britain this three-day period of ludic license was called Shrovetide. Various sports were common, especially games of football. One form of cruel sport prevalent at Shrovetide was pelting cocks and wagering, and this was still practiced in areas of English settlement in Ireland in the late eighteenth and early nineteenth centuries.

## CARNIVAL

As a point of closure for Christmas and Twelfth Night abundance, and a ritual sending off of the old year, Carnival evolved into a late-winter feast day of special importance to the Roman Catholic world.

The underlying theme to Mardi Gras or Carnival is that the days immediately preceding Lent were traditionally set aside for conspicuous feasting. In a medieval context, conspicuous consumption was a show of wealth, since it signaled that the lean days of winter to come were not an inconvenience imposed by financial or by religious considerations.

Since animal flesh was forbidden during the strict fast days of Lent, Shrovetide also became a period when weddings were once popular. This interesting fact is substantiated by medieval wedding records and makes economic sense, if we consider that June (a popular wedding month today) fell in the middle of harvest or planting according to the old calendar. This calendrical sensitivity placed the birth of the child in November, when there was nothing left to do in the fields. Thus Carnival also had an important influence on very basic human lifecycles far and beyond the actual month of celebration. It was also a time of general revelry in village and city alike, with processions of elaborately costumed and masked figures, dancers, and noise makers. It was in essence, a "feast of fools," a time when the usual rules of everyday behavior could be relaxed, even to the extent that such tabooed behavior as cross-dressing could make its appearance in parades with general approval.

European scholarship has meticulously analyzed the masking and de-masking of participants in the traditional Mardi Gras Carnival. On the one side there is a definite affinity to masks representing demons and animals, totemism disguising the living from the spirits of the dead, who were thought to be abroad on this eve of Lenten austerities. On the other hand, the serving of nourishing, satisfying fat foods at Shrovetide expresses the basic idea in European folk culture that one should, in Harvey Cox's words in *The Feast of Fools*, indulge in conscious excess. In some European regions it was customary to eat seven or even nine different kinds of food on Shrove Tuesday. These included butter and milk, roast pork, fish, peas, and

millet. Feasting was sometimes interrupted by "wise" individuals, as evidence of aiding fertility. Fish were folkloric prognosticators of wealth to come—so many scales or eggs, so much the profit. The same benefit was claimed for millet—the more tiny millet grains eaten on Shrove Tuesday, the more coins one could hope for in the future.

The pre-Lenten feasting was thought to betoken an abundant harvest in the coming summer. Because Shrovetide cakes were products of a church festival, they acquired virtues beyond the nutritional. Crumbs were fed to the chicken on Shrove Tuesday so that they would produce more eggs and be protected from predators. Leftovers were also scattered for the angels, foxes, hawks, and martens, undoubtedly with mixed messages to the recipients to ward off danger. Even the Shrovetide lard was used in folk medicine as a wound salve, and ploughshares and wagons were symbolically greased with it before they were first used in the spring farm work.

However, one of the greatest legacies of Shrove Tuesday is the urban carnival which took place in large cities like Rome, Paris, Cologne, Munich, and Basel. They assumed the form of huge processions, with rites of crowning a prince and princess (or king and queen). Similar feast day parades are found throughout the Americas, but especially in Mexico and South America. The most famous of these is the great Carnival parade in Rio de Janeiro, Brazil, an event for which the city prepares throughout the entire year. Much older Carnival traditions can be found in the mountain villages of the Black Forest and in the Austrian Tyrol, where carvers of wooden masks are still working a traditional art form that pre-dates Christianity.

At the time of the Reformation, Protestant countries for the most part gave up traditional Carnival rites connected with the official ecclesiastical celebration. Mumming and masking were in particular dropped, or shifted to Christmas, New Year's Day, and Twelfth Night (Epiphany). This residual mumming was once popular in colonial North America, and survives today as the New Year's Day Mummers Parade in Philadelphia.

*Don Yoder*

Shrovetide was also a period of dietary license, and foods forbidden in Lent were consumed in abundance. Eggs and milk were at one time forbidden in Lent and therefore any supplies had to be used up before Ash Wednesday. On Shrove Monday, in parts of England, meat and eggs were eaten, or gifts of pancakes, flour, eggs, or money to provide Shrove Tuesday fare were col-

lected by children or adults, who often recited a "shroving" verse. Refusal to contribute could result in shard- or stone-throwing, or loud knocking with clubs on doors.

Shrove Tuesday was also known as "Pancake Day" in England. After the Reformation, the Shriving Bell, which had hitherto called parishioners to be shriven, signaled the

Tossing the pancake. An engraving from Mr. and Mrs. Samuel Carter Hall's *Ireland: Its Scenery, Character &c.* (London, 1841). PUBLISHED WITH PERMISSION OF THE FOLKLORE SOCIETY, LONDON.

commencement of revelry and pancake-making. In parts of Wales children formerly collected pancake ingredients, while in the Isle of Man, pancake-making has apparently replaced the older custom of serving oatmeal and gravy for midday dinner and meat and pancakes in the evening.

In Scotland, beef was eaten on Shrove Tuesday (also called "Fastern's E'en") to ensure household prosperity. Oatmeal bannocks enriched with eggs and milk were baked, and, together with the beef broth, were used in marriage divination by the inclusion of a ring to betoken marriage, or other items to indicate the rank or occupation of the future marriage partner. The identity of the beloved might be revealed in dreams induced by placing a bannock under the pillow.

In Ireland, Shrove Tuesday (i.e., pre-Lenten) weddings were formerly popular, a custom seemingly connected to the canonical prohibition on the solemn celebration of the sacrament of matrimony during Lent, and pranks might be played on those still unwed at that time. Shrove Tuesday was especially a household festival, when "nobody should be without meat" (Danaher, p. 42). Pancakes—often including a ring to signify early marriage—were eaten, and pancake-tossing as a form of marriage divination was still practiced in the nineteenth

century in areas of strong English settlement in Ireland from late medieval times.

Relaxation of the austere Lenten regulations meant that it was unnecessary to use up supplies of milk, eggs, and butter on the eve of Lent. Yet pancakes retain their festive connection to Shrove Tuesday. Homemade or commercially produced pancakes remain popular on Shrove or "Pancake" Tuesday in Great Britain. The traditional pancake greaze at Westminster School in London still takes place on Shrove Tuesday: the cook tries to toss a pancake over the pancake bar, and the boy who succeeds in getting the most cake in the ensuing "greaze" or scrimmage is declared the winner.

In Ireland also, pancakes sprinkled with castor sugar and served with a slice of lemon are much enjoyed as a Shrove Tuesday treat and are also a treat, though increasingly with multicultural dimensions, in British and Irish communities in North America, Australia, and New Zealand.

In many parts of Europe, a variety of pastries rich in milk, butter, and eggs and cooked in hot fat are eaten during carnival celebrations. In Slovenian and Croatian Istria, for example, they are termed *fritoli* and *krošule*, while in Sardinia, these doughnut-like pastries are called *zeppole*. They are similar in texture to the small rectangular pastry called *Funkenküchle*, popular during carnival festivities in western Austria, parts of South Tyrol, several areas in Switzerland, and certain regions of southern and western Germany. This latter pastry is made of flour, salt, sugar, and cream, cooked in hot fat, and sprinkled with cinnamon and sugar. It is eaten around a large fire lit on the first Sunday of Lent (*alte Fastnacht*, old eve of fast) since the introduction of the Gregorian calendar in 1582. *Fastnachtuchen* are still popular among the Pennsylvania Dutch. These were originally rectangular or diamond-shaped, but today many are made round like doughnuts.

**SIBERIA.** Siberia occupies a huge territory with a wide variety of climatic conditions and geographic landscapes. Apart from the Russian-speaking Siberians, about one-twentieth of the population consists of aboriginal groups. To better understand the food and meal traditions of the Siberian people, it is necessary to review the geography, climate, and the history of this region.

### Geography and Climate

Siberia occupies about 5.2 million square miles, which roughly corresponds to about 9 percent of Earth's dry land mass. It is bounded by the Ural Mountains in the west and by the Pacific Ocean in the east. To the south lies central Asia, Mongolia, and China, and to the north the Arctic Ocean. For many people Siberia is synonymous with an intensely cold climate, but this image is only partially correct. The climate of most of Siberia is continental, which means there are large temperature differences between summer and winter. The Siberian win-

Detail of *pel'meni* showing the dumplings and various spices added to the broth in which they are boiled. On the right, *smetana* (sour cream), traditionally served with Siberian *pel'meni*. PHOTO BY ILYA VIKTOROVICH LOYSHA COURTESY OF STOLICHNAYA RUSSIAN VODKA.

ter is indeed long and cold, yet summers are fairly warm—warm enough to allow for the cultivation of watermelons in western and southern Siberia. Although there is relatively little precipitation in eastern Siberia, and the winter frost penetrates quite deep, the climate becomes milder and warmer towards the west and south. Due to heavy rainfall, the region is drained by numerous rivers and dotted with lakes filled with a variety of fish.

The Siberian northern coastal region along the Arctic Ocean is occupied by a wide strip of arctic tundra, which is inhabited by an enormous population of reindeer. South of this is a vast area of evergreen pine forest, which gradually changes to fertile *chernozem* (black earth) steppes. The far southeastern part of Siberia, near Manchuria and the Pacific Ocean, consists of subtropical forests.

### Siberian People and History

Much of Siberia (excluding the far north) was united for the first time under the rule of the Mongolian leader Genghis Khan in the beginning of the thirteenth century. Since the Mongolian Empire included China, Persia, and central Asia and stretched as far as Europe, many new culinary ideas from far-off places were introduced. *Pel'meni* and *chaj* (tea) are perhaps the most long-lasting remnants of that period.

Siberian history of the past four centuries has many parallels with the colonization of the Americas. Colonization of Siberia by tsarist Russia began in the 1580s and ended in 1860 with the founding of Vladivostok on the coast of the Sea of Japan. Most of the population of present-day Siberia consists of a mixture of different immigrant ethnicities and people of various aboriginal backgrounds. Siberians of mixed race and ethnic background

refer to themselves as Chaldons and view themselves as an ethnic identity separate from Russian.

Siberia was colonized and settled by a variety of European ethnic groups rather than just by the Russians. During the seventeenth century, settlers included Russians, Komi peoples, Lithuanians, Ukrainians, and Byelorussians, and small numbers of Germans, Greeks, and even a few baptized Tartars and Turks. Later on, there were waves of other immigrants, some of whom were exiled forcibly. These included Swedish prisoners of war, German and other European technical specialists, Polish, Lithuanian, Byelorussian, Ukrainian, and Jewish exiles from rebellious Polish territories, as well as settlers who came from the central regions of Russia, Ukraine, and Byelorussia after the abolishment of serfdom in 1861. Colonization was especially intensive during the construction of the Trans-Siberian railway (1891–1905). The population of Siberia reached almost ten million people by 1914.

Since the political exiles who came to Siberia in the nineteenth century were generally well educated, many of them became involved in the improvement of truck

farming, grain growing, the cultivation of oil-yielding crops (such as hemp), and the introduction of new vegetables and modern methods of cultivation. Each of the immigrant groups brought something of their own cookery to the big Siberian stewpot, thus enriching what is now called Siberian cuisine. For example, Korean spicy carrot salads, stuffed fish baked in the oven, and stewed sour cabbage and pork became Siberian national dishes.

Prior to Russian colonization of Siberia, local ethnic groups of various origins populated the region, including Turkic, Finnic, Mongolic, and other tribes. Some of these peoples intermarried with Europeans and some ethnic groups remained discrete, but in any case, colonists adopted many local food traditions through mixed marriages or through daily contact.

### Cookery of the Chaldony

Due to the huge size of the country, almost limitless natural resources, a surplus of free land, and the absence of serfdom, life in the wilderness of Siberia was always more free, happier, and more prosperous than life in European Russia. It was easy to protect one's freedom in Siberia—

when faced with bureaucratic oppression, one could simply leave and settle in remote places or deeper forests. Because of this freedom and abundant local and foreign food products, Chaldon cuisine originated as a rich mixture of European and aboriginal traditions.

Before the Bolshevik Revolution, the Chaldon people produced basic food products on their own farms. These foods included dairy products, meat, vegetables, eggs, breads and other cereal products, vegetable oils, as well as mushrooms, wild berries, pine nuts, fish, and game. Although every family possessed hunting guns and traps, game was not central to the Siberian diet. Food was stewed, boiled, or baked in a Russian oven or fried in oil or drawn butter.

**Breads and other cereal and legume products.** Chaldon farmers grew rye, barley, oats, buckwheat, millet, peas, and beans. Wheat was raised in the southern regions, such as Altay. Wheat flour of very high quality, which was used for cookies and cakes, was usually bought at market fairs in large cities.

Every village family and many city households made their own rye, barley, and wheat breads in a round or *kalatch* (padlock-shaped) form; some families had wooden bread molds. Bread flour was mixed with milk and home-made hop yeast and was left standing over night. In the morning, when the bread dough was finished, eggs, *postnaya maslo* (Lenten oil), and milk were often added to the bread. Wealthy families might have used pine-nut oil instead—such bread had a unique flavor and could be kept longer than usual. During times of food shortages, some people baked a green emergency bread made from flour and a large proportion of ground dried nettle leaves.

**Kasha.** Kasha is the Russian word for gruel or porridge. It is used to describe any kind of boiled cereals, peas, beans, other seeds, or even potatoes and vegetables. Kasha can be made sweet or salty, and it can contain almost any kind of additions, like meat, milk, nuts, fresh or dry fruits, and even pumpkin. Kasha can be made from a mixture of different seeds and/or other components that are boiled or baked in an oven. It is eaten hot or cold, as a main dish or as a garnish, plain or with the addition of fruit jams, or diluted with fresh milk if buckwheat is used.

During the first part of the twentieth century, Siberians made many different kashas from barley, millet, or oats. Peas, string beans, and fava beans were also used. Rice was uncommon and used only on special occasions—unlike all other Orthodox Christians who use wheat for *kut'ya* (a funeral dish), the Chaldons make *kut'ya* from rice and raisins.

**Pirogi, pirozhki, and bliny.** Leavened dough was widely used for *pirogi* (large pies) and *pirozhki* (small pies). Pirozhki could be fried or baked and stuffed with potatoes, carrots, green onion and eggs, liver, minced meat, fish, or fresh or dried berries (black currant, raspberry, bird cherry, haws) mixed with malt. The Siberian ana-

logue of pizza was a round, flat pie called *shangi*, which was topped with cottage cheese and sour cream and then baked. Another round pie, called *beliash*, was stuffed with meat, closed up, and fried. *Beliash* can be traced to a Tartar heritage, since in Kazan tartar cookery there was a meat pie called *belish*. The traditional large holiday pie of Chaldons, often called *kurnik*, was made with fish or chicken.

There are also sweet holiday open-faced berry-pies (usually made with black currant).

Many different recipes exist for *bliny* (large thin pancakes) and *oladyi* (smaller pancakes of thicker dough usually oval in shape). These could be made of wheat or rye, leaven or unleavened, and some buckwheat flour, milk, and eggs. Oil and honey could also be added. Once they were made, *bliny* could be stuffed with caviar and eaten cold, or filled with cottage cheese or meat and then baked in the oven or fried. Usually people had a separate frying pan or two for pancakes, and only a pigeon wing was used to grease the pan.
